Abstract

As the death toll of Coronavirus disease 19 (COVID-19) continues to rise worldwide, it is imperative to explore novel molecular mechanisms for targeting SARS-CoV-2. Rather than looking for drugs that directly interact with key viral proteins inhibiting its replication, an alternative and possibly add-on approach is to dismantle the host cell machinery that enables the virus to infect the host cell and spread from one cell to another. Excellent examples of such machinery are host cell proteases whose role in viral pathogenesis has been demonstrated in numerous coronaviruses. In this review, we propose two therapeutic modalities to tackle SARS-CoV-2 infections; the first is to transcriptionally modulate the expression of cellular proteases and their endogenous inhibitors and the second is to directly inhibit their enzymatic activity. We present a nonexhaustive collection of clinically investigated drugs that act by one of these mechanisms and thus represent promising candidates for preclinical in vitro testing and hopefully clinical testing in COVID-19 patients.

KEYWORDS

adjunctive therapy, clinical trial, COVID-19, proteases, SARS-CoV-2

1 | INTRODUCTION

Coronavirus disease 19 (COVID-19) pandemic is one of the major challenges that is currently facing human societies throughout the globe. At the time of writing this review, the number of confirmed cases according to the World Health Organization (WHO) is approaching 55 million and the death toll is exceeding 1.3 million worldwide.¹ COVID-19 is caused by severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection in the respiratory tract. Many susceptible patients progress to a severe form of the disease

that is characterized by an acute respiratory distress syndrome (ARDS),² which severely compromises their respiratory function and often causes organ failure and death. Understanding the mechanism by which the virus infects its host cells in the respiratory tract and spreads through the lung tissue causing its damage is of extreme importance to find an effective treatment. The key viral protein that enables members of the coronavirus family including SARS-CoV-2 to infect their host cells is the spike (S) protein. It is the largest structural protein existing in the virus particles with an overall length ranging between 1200 and 1400 amino acids and is organized into

Abbreviations: ARDS, acute respiratory distress syndrome; COVID-19, Coronavirus disease 19; SARS-CoV-2, syndrome coronavirus-2; WHO, World Health Organization.

homotrimers that are integrated into the viral envelope giving rise to its characteristic corona-shaped structure.³ It possesses a large ectodomain, a small transmembrane domain, and a short endodomain. Like all class I viral fusion proteins, the S protein ectodomain is divided into two functional domains: S1 domain which binds to host cell receptors and S2 domain which mediates the fusion between the viral envelope and the host cell membrane. In order for the fusion machinery of the S2 domain to be active, the S protein has to undergo proteolytic processing by a variety of host cell protease enzymes that are able to cleave its ectodomain at a number of specific sites (Figure 1B). Two of these cleavage sites have been well characterized in SARS-CoV-1, namely the S1/S2 site at the boundary

between these two domains and the S2' site which exists within the S2 domain itself⁴ (Figure 1A). Likewise, a multibasic cleavage site at the S1/S2 boundary has been characterized in the SARS-CoV-2 S protein.⁵ It is worth to mention that these protease-catalyzed cleavage events can take place on the cell surface before viral entry into its host cell, inside endosomes during viral entry and in the cytosol during viral protein synthesis by the infected cell. This is why host cell proteases are believed to play a pivotal role in the pathogenesis of many human coronaviruses as well as other pneumotropic viruses such as influenza.

2 | HOST CELL PROTEASES AS POTENTIAL DRUG TARGETS

Here, the focus is on protease enzymes that have been implicated in the proteolytic activation of SARS-CoV-1 and 2 S proteins since both strains were shown to be very similar in terms of genomic sequence homology, infection mechanism and ensuing pathology.⁸ These enzymes include **trypsin**, **elastase**, thermolysin, **cathepsin B**, **cathepsin L**, transmembrane serine proteases (TMPRSS), plasmin, and **factor Xa**. All of these proteases were reported to cleave the S protein in vitro at the S1/S2 or S2' sites or both.⁹ Of particular importance is **TMPRSS2** which was shown to associate with **ACE2**, a host cell receptor for SARS-CoV-1, and form complexes that improve viral entry at the cell surface.¹⁰ Recently, SARS-CoV-2 was also shown to utilize the same ACE2

FIGURE 1 An illustration of the two cleavage sites of the Spike (S) proteins of SARS-CoV-1 and SARS-CoV-2 and the host cell proteases that can possibly cleave them. (A) Schematic representation of SARS-CoV-1 S protein with its functional domains (RBD, receptor binding domain; RBM, receptor binding motif; TD, transmembrane domain) and its two proteolytic cleavage sites (S1/S2, S2'). Amino acid sequences around the two protease recognition sites (red) are indicated for both S proteins of SARS-CoV-1 and SARS-CoV-2 (asterisks indicate conserved residues). Arrowheads indicate the cleavage site. (copied with permission from Figure 1A by Hoffmann and colleagues⁶). (B) A table listing host cell proteases that are reported to cleave S proteins of coronaviruses together with their subcellular locations, classification according to the Nomenclature Committee of the International Union of Biochemistry and Molecular Biology (NC-IUBMB) and their common recognition sequences with the cleavage site indicated by a downward arrow. Amino acid residues on the N-terminal end of the cleavage site are designated P1, P2, P3,...etc, while those on the C-terminal end are designated P1', P2', P3'...etc "X" denotes any amino acid residue, "hydrophobic" denotes Ala, Val, Leu, Ile, Phe, Trp or Tyr, "aromatic" denotes Phe, Trp, His or Tyr and "positive" denotes Lys, Arg or His⁷

FIGURE 2 A diagram illustrating the different drug candidates, their targets and mechanisms of action. Host cell proteases depicted here are reported to proteolytically cleave the S protein of coronaviruses which is an essential step to initiate the fusion process between viral and epithelial cell membranes. Three categories of drugs are described; drugs that downregulate the expression of protease enzymes, drugs that directly inhibit their enzymatic activity, and drugs that upregulate the expression of endogenous protease inhibitors. All elements used in this illustration come from the Reactome icon library (<https://reactome.org/icon-lib>). Protein structures of host cell proteases and protease inhibitors were obtained from UniProt knowledgebase (<https://www.uniprot.org/>) and Protein Data Bank (<https://www.rcsb.org/>). Abbreviations: TMPRSS, transmembrane serine protease; HDAC, histone deacetylase; HAI-1, hepatocyte growth factor activator inhibitor type 1

receptor for entry and TMPRSS2 protease activity to prime its S protein⁶ (Figure 2). In addition, the host cell protease furin was shown to cleave the SARS-CoV-2 S protein at the S1/S2 site which is an essential event for spike-driven viral entry into lung cells.⁵ Moreover, the endosomal cysteine proteases cathepsin B and L were found to participate in processing SARS-CoV-1 and 2 S proteins enabling them to be primed even in the absence of TMPRSS2 activity.^{6,11} Beside proteases, host cells are equipped with a collection of natural protease inhibitors that control the activity of many of the above-mentioned proteolytic enzymes such as alpha1 antitrypsin (AAT) which inhibits trypsin and elastase and hepatocyte growth factor activator inhibitor type 1 (HAI-1) and type 2 (HAI-2) which regulate activities of transmembrane serine proteases including TMPRSS2.¹² Interestingly, HAI-2 was reported to inhibit influenza virus H1N1 infection in cell culture, and its administration showed protective effects in a mouse model of influenza.¹³ This has been attributed to its effective inhibition of the proteolytic cleavage of influenza virus hemagglutinin (HA) which is another class I viral fusion protein that shares many common features with the coronavirus S protein. Similar to the S protein, HA is synthesized as an intact precursor that gets cleaved by host cell proteases giving rise to two functional subunits HA1 and HA2. HA1 resembles the S1 domain of S protein where it binds to sialic acid receptors on the host cell surface, while HA2—just as the S2 domain—contains a fusion peptide that gets exposed upon cleavage initiating the fusion process between viral and host cell membranes.⁹ Beside HAI-1 and HAI-2, the serine protease inhibitor, plasminogen activator inhibitor 1 (PAI-1) was likewise shown to inhibit HA cleavage and prevent H1N1 influenza virus replication both *ex vivo* and *in vivo*.¹⁴

In light of what is known so far about proteases and their inhibitors, two treatment approaches are proposed to control SARS-CoV-2 infections. The first approach is to use transcriptional suppressors that downregulate the expression of protease enzymes on the gene level or alternatively transcriptional activators that enhance the expression of the naturally occurring protease inhibitors. The second approach is to target host cell proteases directly through the use of small-molecule compounds or proteins that are known to inhibit their enzymatic activity. In this review, we discuss these two approaches and present a number of drug candidates that act by one or more of these mechanisms, and as such have a great potential for clinical use to limit viral infectivity and spread.

One obvious limitation of these targeting approaches is the fact that host cells are equipped with a wide range of proteolytic enzymes—as discussed above—that were found to cleave coronavirus S protein. Targeting one specific enzyme with an inhibiting molecule may not be sufficient to stop viral spread due to the abundance of other proteases. Despite this drawback, it is obvious at least from a number of *in vitro* and *in vivo* studies that cleavage of S protein by specific proteases appears to be more important for viral pathogenicity than by others and that inhibiting one of these enzymes can significantly block viral entry into its host cells. One particular example is TMPRSS2 where its inhibition in human lung cell lines clearly

blocked their infection with SARS-CoV-2 *in vitro*.⁶ The same concept applies to other kinds of viruses that possess class I viral fusion proteins as influenza A where inhibition of trypsin-like serine proteases using the naturally occurring protease inhibitors HAI-2 and PAI-1 displayed antiviral activity both *in vitro* and *in vivo*.^{13,14} Furthermore, combination antiprotease therapy targeting more than one protease enzyme simultaneously is another possibility to enhance the antiviral activity of such drugs. Some drug combinations with acceptable safety profiles are discussed below to serve this purpose.

3 | DRUGS AFFECTING TRANSCRIPTIONAL REGULATION OF HOST CELL PROTEASES OR PROTEASE INHIBITORS

3.1 | Drugs targeting androgen and estrogen receptors

TMPRSS2 gene expression is known to be activated by the androgen receptor.¹⁵⁻¹⁷ For this reason, drugs that block this receptor are believed to interfere with TMPRSS2 expression resulting in its downregulation. In line with this, enzalutamide (an androgen receptor antagonist), estradiol, and the phytoestrogen genistein were recently reported to downregulate the expression of TMPRSS2 using RNA sequencing data derived from human prostate, breast, and endometrial cancer cell lines.¹⁸ On the other hand, testosterone and metribolone (a synthetic androgen) were shown to significantly increase its expression in human prostate cancer cells. Consistent with these findings, treatment of prostate cancer cell lines with enzalutamide again resulted in reduced TMPRSS2 mRNA expression measured by real-time quantitative polymerase chain reaction (qPCR).¹⁹ Moreover, fulvestrant (an estrogen receptor antagonist) was found to upregulate TMPRSS2 expression in a breast cancer cell line using single-cell RNA sequencing data.¹⁸ Notably, the authors demonstrated that genes that were highly correlated with TMPRSS2 expression in RNA sequencing data obtained from human lung tissues were significantly enriched for androgen and estrogen response hallmark genes. This provides sound evidence that androgen and estrogen receptors are important transcriptional regulators of TMPRSS2 gene in human lung cells. It is worth mentioning here that estrogen receptor signaling played a protective role in female mice infected with SARS-CoV-1 where ovariectomy or treating the mice with an estrogen receptor antagonist led to increased mortality.²⁰ Moreover, there is a growing body of evidence suggesting that male sex is a predisposing factor to COVID-19. One possible mechanism that could contribute to this predisposition is the increased expression of transmembrane serine proteases, particularly TMPRSS2, in response to male sex hormones.^{21,22}

Regarding their clinical utility, both enzalutamide and estradiol have a well-established clinical profile making them suitable for trial in COVID-19 patients. Enzalutamide is clinically approved for treatment of patients with castration-resistant prostate cancer and

metastatic castration-sensitive prostate cancer.²³ The most common adverse effects associated with its use are peripheral edema, hyperglycemia, hyponatremia, hypermagnesemia, upper respiratory tract infection, asthenia, back pain, disturbed bowel movement, and arthralgia.²³ On the other hand, oral administration of estrogen and its synthetic derivatives has long been used for contraception and treatment of menopause-related conditions such as vaginal atrophy and osteoporosis.²⁴ Adverse effects of systemic estradiol include vaginal hemorrhage, edema, headache, gastrointestinal discomfort, mastalgia, deep vein thrombosis, and nasopharyngitis.^{25,26} Given such toxicity profiles, we propose that enzalutamide can be used at an oral daily dose of 160 mg in male patients especially those with a compelling indication as prostate cancer. Likewise, estradiol combined with a progestin can be administered at an oral daily dose of 1-2 mg to female patients.

3.2 | 5-alpha reductase inhibitors

5-alpha reductase inhibitors are another class of drugs that influence intracellular androgen signaling and are clinically used to treat conditions with excessive androgen production such as benign prostatic hyperplasia and male pattern hair loss.²⁷ By inhibiting 5-alpha reductase enzyme, these drugs prevent the conversion of testosterone to the more active dihydrotestosterone and hence attenuate androgen-mediated cellular responses.²⁷ This in turn can lead to a reduction in the expression of androgen-regulated genes including *TMPRSS2*. Indeed, treatment with the clinically approved inhibitor dutasteride was found to reduce *TMPRSS2* expression in microdissected prostate epithelial tumor tissues as measured by both gene expression microarrays and real-time PCR.²⁸ This drug also significantly decreased *TMPRSS2* staining in the neoplastic prostate epithelium. With regard to its safety, dutasteride is generally well tolerated and causes no serious adverse effects. Its use is associated with decreased libido, ejaculation disorder, and erectile dysfunction, however, these effects are usually mild and decrease over time.²⁹ In terms of applicability to COVID-19 patients, we propose this drug can be used at an oral daily dose of 0.5 mg. However, it is important to mention that it is contraindicated in pregnant women or women who may become pregnant due to potential risk to a male fetus.³⁰

3.3 | Histone deacetylase (HDAC) inhibitors

HDAC inhibitors are compounds that inhibit histone deacetylase enzyme which catalyzes the removal of acetyl groups from both histone and nonhistone proteins including transcription factors. Inhibition of these deacetylation reactions alters the compactness of the chromatin structure and the transcriptional regulation of many genes that control the cell cycle, proliferation, and apoptosis.³¹ For this reason, HDAC inhibitors have been used as anticancer drugs. Among the genes whose expression is altered by HDAC

inhibition are those encoding the serine protease inhibitors HAI-1 and HAI-2. By querying the connectivity map (CMAP) drug perturbation signatures,³² we found that the classical HDAC inhibitors apicidin and trichostatin A increased the expression of *SPINT1* and *SPINT2* genes which encode HAI-1 and HAI-2, respectively, in human lung cancer cell lines as measured by L1000 gene expression assay. Similarly, a number of second-generation HDAC inhibitors (vorinostat, panobinostat, and mocetinostat) were found to increase the expression of one of these two genes or both in the same cell lines.

In the matter of clinical relevance, vorinostat and panobinostat are both clinically approved for treatment of T-cell lymphoma and multiple myeloma, respectively. In terms of safety, the most common adverse effects associated with vorinostat are fatigue, nausea, diarrhea, thrombocytopenia, anorexia, and dysgeusia. Pulmonary embolism, anemia, and squamous cell carcinoma of the skin are more severe toxicities that were reported in less than 5% of patients.^{33,34} Similarly, panobinostat use is linked to asthenia, fatigue, and diarrhea, however, it is also associated with pneumonia, peripheral neuropathy and the more serious myelosuppression which manifests as thrombocytopenia, neutropenia, and lymphopenia.³⁵ Given the blood toxicity profiles of these drugs, we give them less priority for clinical investigation in COVID-19 despite their seemingly desirable effects on host cell proteases as we believe their risk-benefit ratio does not favor their use.

3.4 | Cardiac glycosides

Long known for their positive inotropic effect, cardiac glycosides have been used for managing patients with cardiac muscle failure for a very long time. However, because of their narrow therapeutic index and relatively high risk of toxicity associated with their prolonged use, their clinical indications are now restricted.³⁶ Interestingly, these compounds may still provide some benefits for patients with coronavirus infections. By examining a large collection of RNA sequencing data, Wang and colleagues showed that digitalis-like compounds including digoxin and proscillaridin A markedly reduced expression of the endosomal cathepsins B and L in human thyroid cancer cells.³⁷ This effect can limit S protein processing and priming in the endosomal compartments of infected host cells.

Digoxin use has long been associated with gastrointestinal adverse effects, visual disturbances, and cardiovascular toxicity including cardiac arrhythmia, tachycardia, and heart block.³⁸ Despite its potential for cardiovascular toxicity, we suggest that digoxin can be tested in COVID-19 patients at an oral daily dose of less than 0.125 mg such that its serum concentration is kept below 1 ng/mL. At such low concentration, digoxin is not only associated with minimal adverse effects, but also exerts beneficial hemodynamic, neurohormonal, and clinical effects in patients with congestive heart failure and other cardiovascular diseases.³⁹ Accordingly, we encourage testing digoxin in COVID-19 patients with preexisting cardiovascular conditions such as heart failure.

4 | DRUGS THAT DIRECTLY INHIBIT HOST CELL PROTEASE ACTIVITY

4.1 | Human neutrophil elastase (HNE) inhibitors

Elastase and other serine proteases released from neutrophils at inflammation sites are believed to play an important role in the pathogenesis of chronic obstructive pulmonary disease (COPD), cystic fibrosis (CF), pneumonia, and acute lung injury which may result from viral infections.^{40,41} These diseases are usually accompanied by a local imbalance between proteases (serine proteases, cathepsins, and metalloproteases) and antiproteases (alpha1 antitrypsin, a2-macroglobulin, cystatins, and tissue inhibitors of metalloproteinases). This increased activity of proteolytic enzymes particularly elastase leads to the breakdown of elastin and other components of the lung connective tissue and induce the release of pro-inflammatory cytokines augmenting the destructive inflammatory response.⁴² In addition, elastase was shown to activate the SARS-CoV-1 S protein and shift the viral entry to a low pH-independent route.^{43,44} Therefore, inhibition of elastase would serve two purposes; the first is to prevent S protein cleavage and activation and the second is to ameliorate elastase-mediated lung damage. A vast range of HNE inhibitors have already been developed to treat various lung inflammatory conditions including COPD, CF, bronchiectasis, acute lung injury and ARDS⁴¹ and are now being tested in clinical trials. We believe these candidates would be extremely beneficial in the management of patients with severe SARS-CoV-2 infection.

To date, there are no known severe toxicities that could limit the use of the HNE inhibitor [sivelestat](#) in COVID-19 patients. Adverse effects with the highest reported incidence in clinical trials are hepatobiliary disorders including elevated blood bilirubin and liver enzymes.⁴⁵ Such safety profile makes this drug of particular interest for clinical testing in COVID-19 patients upon hospital admission. Intravenous administration of sivelestat to hospitalized patients at a dose of 0.2 mg/kg per hour is proposed as a preventative treatment option to attenuate ARDS associated with the viral infection and improve the mortality rate in patients with advanced disease.^{46,47}

4.2 | Alpha1 antitrypsin (AAT)

This alpha globulin glycoprotein is one of the most widely known members of the SERPIN superfamily of serine protease inhibitors. It is mainly synthesized in the liver by hepatocytes and released into the bloodstream. It is also synthesized by the pancreas, lung alveolar cells, vascular endothelium, and intestinal epithelium.⁴⁸ Genetic deficiency of AAT leads to a wide range of pathologies affecting mainly the lungs, liver, and blood vessels.⁴⁸ AAT possesses anti-inflammatory, immunomodulatory, and anti-infection activity. It promotes tissue repair and protects tissues from damage induced by proteolytic enzymes released from inflammatory cells.⁴⁸ Equally important, AAT inhibits the activity of trypsin and elastase which are known to

cleave and activate the S protein of SARS-CoV-1⁹ and possibly also SARS-CoV-2. Similar to HNE inhibitors, these properties make AAT a promising candidate for managing COVID-19 patients.⁴⁹

Like sivelestat, the toxicity profile of AAT therapy should not limit its use in COVID-19 patients. The most common adverse reactions are typical of intravenous infusion of proteins and include fever, chills, urticaria, nausea, vomiting, and fatigue.⁵⁰ Dyspnea, anaphylactic reactions, and exacerbation of heart failure were also reported in patients receiving AAT therapy, however, incidence of these events was rather low.⁵⁰ Accordingly, intravenous infusion of AAT at a dose of 60 mg/kg weekly is proposed as another preventative measure that can protect against ARDS and reduce mortality in hospitalized COVID-19 patients.

4.3 | Inhibitors of the clotting factor Xa

The clotting protein factor Xa is a serine protease that is derived from the hydrolysis of its precursor factor X which takes place via two principal pathways.⁵¹ The first is the extrinsic pathway which occurs at the surface of a damaged endothelium and macrophages and involves activation of factor X by factor VII/VIIa in association with a membrane-bound cofactor, tissue factor (TF). The second is the intrinsic pathway in which factor X is activated on the platelet surface by a membrane-bound tenase complex comprising factor IXa, its cofactor factor VIIIa, and calcium ions. Factor Xa then activates prothrombin to thrombin eventually leading to blood clotting. In the context of SARS-CoV-1 infections, factor Xa was found to cleave the viral S protein at the S1/S2 boundary and promote entry into host cells.⁵² Hence, drugs that act as inhibitors of factor Xa are considered protective against S protein priming and viral entry. Three factor Xa inhibitors ([rivaroxaban](#), [apixaban](#), and [edoxaban](#)) are now approved as novel oral anticoagulants and can be used as a replacement for the vitamin K antagonist warfarin.⁵³

Given that COVID-19-associated coagulopathy (CAC) has been reported in several studies,^{54,55} the use of factor Xa inhibitors may offer additional benefit by preventing development of venous thromboembolism (more common in COVID-19 patients) and arterial thromboembolism (less common) especially among seriously or critically ill patients with COVID-19.⁵⁶ A recently published retrospective analysis involving 4389 hospitalized COVID-19 patients reported a lower mortality and intubation in the anticoagulation group compared to the control group.⁵⁷ A number of clinical trials are underway to investigate the effectiveness of heparin and low molecular weight heparin both in prophylactic and therapeutic doses to prevent thromboembolism in COVID-19 patients.⁵⁸⁻⁶⁴

Although the pathogenesis of hypercoagulability in COVID-19 patients is not fully understood, it has been proposed that all three components of Virchow's triad including endothelial injury, stasis, and hypercoagulable state are included.^{54,56} Elevated levels of a number of prothrombin factors including von Willebrand factor (vWF), factor VIII, D-dimer, fibrinogen, neutrophil extracellular traps, prothrombotic microparticles, and anionic phospholipids are believed to be responsible for CAC. We believe that Xa inhibitors

TABLE 1 A list of clinically approved and/or investigational drug candidates that target host cell proteases via transcriptional regulation or direct inhibition of protease activity together with their clinical indications, available routes of administration, and ongoing clinical trials in COVID-19 patients

Drug candidates	Targeted host cell factor	Reported mechanism	Clinical indications	Routes of administration	Clinical trials in COVID-19 patients**
Androgen receptor antagonists (enzalutamide)	TMPRSS2	Downregulation of protease expression ^{18,19}	*Treatment of metastatic castration-resistant prostate cancer	Oral	NCT04475601 NCT04456049
Estrogen receptor agonists (estradiol)	TMPRSS2	Downregulation of protease expression ¹⁸	*Treatment of moderate to severe vasomotor symptoms and vulvar and vaginal atrophy due to menopause *Prevention of postmenopausal osteoporosis *Treatment of estrogen deficiency due to hypogonadism, castration or primary ovarian failure *Oral contraception for preventing pregnancy (in combination with synthetic progestins)	Oral, topical, transdermal and vaginal	NCT04359329 NCT04539626
5-alpha reductase inhibitors (dutasteride)	TMPRSS2	Downregulation of protease expression ²⁸	*Treatment of symptomatic benign prostatic hyperplasia	Oral	NCT04446429
Camostat and nafamostat mesilate	TMPRSS2	Inhibition of protease activity ^{10,72}	†Treatment of chronic pancreatitis in Japan ⁹⁴⁻⁹⁶ †Treatment of COVID-19 (indication under investigation)	Oral	Camostat mesilate (149 trials eg, NCT04583592, NCT04353284 & NCT04455815) Nafamostat mesilate (6 trials eg, NCT04418128, NCT04623021 & NCT04352400)
HDAC inhibitors (trichostatin A, vorinostat and panobinostat)	HAI-1 and HAI-2	Upregulation of protease inhibitor expression (through query of CMAP drug perturbation signatures ³²)	*Vorinostat is approved for treatment of cutaneous manifestations in patients with progressive cutaneous T-cell lymphoma *Panobinostat is approved for treatment of multiple myeloma	Oral	None
Cardiac glycosides (Digoxin)	Cathepsin B and L	Downregulation of protease expression ¹⁸	*Treatment of mild to moderate heart failure in adults *Control of ventricular rate in patients with chronic atrial fibrillation *Increasing myocardial contraction in children with heart failure	Oral, intramuscular and intravenous	None
Glycopeptide antibiotics (Teicoplanin)	Cathepsin L	Inhibition of protease activity ^{79,80}	*Treatment and/or prophylaxis of bacterial infections caused by susceptible microorganisms	Oral, intramuscular and intravenous	None

(Continues)

Table 1 (Continued)

Drug candidates	Targeted host cell factor	Reported mechanism	Clinical indications	Routes of administration	Clinical trials in COVID-19 patients**
Dexamethasone	Cathepsin B and L	Inhibition of protease activity ^{83,84}	<p>*As otic suspension for treating inflammation associated with bacterial infections in acute otitis media and acute otitis externa (in combination with ciprofloxacin)</p> <p>*As intramuscular and intravenous injections for treating a variety of endocrine, rheumatic, dermatologic, allergic, ophthalmic, gastrointestinal, respiratory, hematologic, neoplastic, edematous, and other conditions.</p> <p>*As oral tablets for treatment of multiple myeloma</p> <p>*As intravitreal implant for treatment of some forms of macular edema and non-infectious posterior uveitis</p> <p>*As various ophthalmic formulations for treating inflammatory conditions of the eye</p> <p>†Management of COVID-19 patients with severe respiratory symptoms (indication under investigation⁹⁷)</p>	Numerous routes of administration are available	2114 trials eg. NCT04504032, NCT04508023, NCT04416048 & NCT04324463) Apixaban (NCT04498273 & NCT04512079) Edoxaban (NCT04542408 & NCT04516941)

Note: Indications denoted by * are FDA approved and those denoted by † are currently under investigation. Information concerning clinical indications and available routes of administration was obtained from the DrugBank online database (<https://www.drugbank.com/>). **All clinical trial information for the drug candidates was obtained from ClinicalTrials.gov, number of clinical trials and their identifiers are specified whenever applicable (<https://clinicaltrials.gov/>, accessed 17 November 2020).

can act by a dual mechanism; by inhibiting viral entry and preventing CAC.⁶⁵

4.4 | Other important candidates with serine/cysteine protease inhibitory activity

An additional set of small molecule and protein inhibitors of serine proteases, especially TMPRSS2, have been thoroughly reviewed.⁶⁶ Of particular importance are the two TMPRSS2 inhibitors **camostat** and **nafamostat** mesilate. Camostat has shown remarkable in vitro antiviral activity against H1N1 influenza, SARS-CoV-1 and the Middle East respiratory syndrome-related coronavirus (MERS-CoV) infections in human tracheal epithelial cells, human lung cancer cells and monkey kidney epithelial cells.^{10,67,68} Moreover, camostat exhibited in vivo antiviral activity against H1N1 influenza and SARS-CoV-1 in mouse models.⁶⁹⁻⁷¹ It was also recently shown that camostat can block SARS-CoV-2 entry into human lung cancer cells and therefore constitutes a potential therapeutic option.⁶ Interestingly, nafamostat was found to be more effective than camostat in blocking MERS-CoV entry and replication in host cells.⁷² Another specific TMPRSS2 inhibitor with great potential is the mucolytic agent bromhexine hydrochloride⁷³ whose high safety profile makes it an excellent candidate for clinical testing against SARS-CoV-2. In addition, other serine protease inhibitors showed remarkable antiviral effects against H1N1 influenza infections both in vitro and in vivo by virtue of their ability to block HA cleavage and activation, and thus are good candidates to be tested against SARS-CoV-2 infections. These include ovomucoid, **aprotinin** and 4-(2-aminomethyl) benzenesulfonyl fluoride hydrochloride.^{71,74-76} It is worth mentioning here that a number of FDA-approved drugs are reported to inhibit the activity of cathepsins specifically cathepsin L and these have been recently reviewed and proposed as potential candidates for the treatment of COVID-19.⁷⁷ Examples include the antileprotic drug clofazimine,⁷⁸ the antibiotic teicoplanin,^{79,80} the anti-HIV saquinavir,⁸¹ the antituberculosis rifampicin,⁷⁸ the antioxidant astaxanthin,⁸² the anti-inflammatory dexamethasone,^{83,84} and the antimalarial chloroquine.^{85,86} Although the latter chloroquine and its derivative hydroxychloroquine are currently used in treatment protocols of COVID-19, it was recently reported that hydroxychloroquine did not reduce mortality in hospitalized COVID-19 patients compared to standard of care.^{87,88}

Among all aforementioned candidates, camostat and nafamostat are currently receiving the most attention in terms of clinical testing in COVID-19. Camostat administration was associated with mild adverse effects when used in 95 patients suffering from dyspepsia associated with nonalcoholic pancreatic disease at a dose of 200 mg three times daily for 2 weeks. Only two of the 95 patients developed very mild side effects.⁸⁹ Similarly, nafamostat did not show any serious adverse effects when administered to patients with severe acute pancreatitis at a dose of 240 mg/day intravenously or via arterial infusion.⁹⁰ Yet, the safety and efficacy profile of these two drugs in COVID-19 patients is still being assessed in 11 trials with larger

sample sizes (Table 1). In addition to TMPRSS2 inhibitors, the endosomal cathepsin L inhibitor teicoplanin is considered a potential antibiotic for treating secondary bacterial infections associated with SARS-CoV-2. The adverse effects most frequently associated with teicoplanin treatment are local and hypersensitivity reactions, such as itching and drug fever; anaphylactic reactions including the "red man syndrome" are uncommon. Teicoplanin is also less likely than vancomycin to cause nephrotoxicity, especially when administered in combination with an aminoglycoside.⁹¹⁻⁹³

5 | COMBINATION PROTEASE-TARGETING THERAPY

As discussed earlier, combinatorial protease-targeting therapy is propounded to tackle the problem of redundancy of host cell proteases that can process and activate coronavirus S protein. Targeting more than one protease enzyme using a drug combination is likely to be more effective in combating viral spread than inhibiting just a single enzyme. We propose here a number of protease-targeting drug combinations that we believe would provide potential therapeutic benefit for hospitalized COVID-19 patients. Inhibitors of the membrane-bound TMPRSS2 are of particular importance because of the key role this enzyme plays in early S protein processing at the cell surface.⁶ Combining such inhibitors with drugs targeting the extracellular proteases as trypsin and elastase or those targeting the endosomal proteases as cathepsin L is a considerable option as such combinations would provide an adequate coverage of host cell proteases across the different compartments (Figure 2). A TMPRSS2 inhibitor as camostat or nafamostat and an elastase inhibitor as sivelestat are recommended to be administered to all hospitalized patients starting on day 1 of admission. This may help limit viral spread in the respiratory tract in the early days of admission and at the same time protect against ARDS and viral-induced inflammatory lung damage.^{45,46} Another alternative combination with the same rationale would be oral dutasteride (which acts via TMPRSS2 downregulation) instead of camostat together with IV sivelestat. When it comes to targeting androgen receptor signaling and TMPRSS2 expression, the 5-alpha reductase inhibitor dutasteride is preferred over the androgen receptor antagonist enzalutamide because its adverse effects are generally less severe. IV AAT is also suggested for administration with TMPRSS2 inhibitors as an alternative to sivelestat since both of them are expected to exert similar beneficial effects in terms of mitigating elastase-induced lung damage and inflammation.^{46,49} Dexamethasone (which inhibits cathepsins B and L^{83,84}) can be added to these combinations once the patient develops a severe respiratory deficit and requires oxygen support since this drug has already been shown to reduce mortality in this particular clinical scenario.⁹⁷ Another potential candidate to add to such combinations is the oral secretolytic agent bromhexine hydrochloride which showed inhibitory activity against TMPRSS2 and

is generally safe to use.⁷³ Moreover, we recommend the use of the glycopeptide antibiotic teicoplanin in hospitalized patients who develop pneumonia as a result of secondary bacterial infections as this antibiotic was shown to inhibit cathepsin L^{79,80} and thus may help to control the viral infection as well.

The question concerning the optimal timing for administration of antiprotease combinations is definitely pivotal. We propose that oral TMPRSS2-targeting drugs such as camostat, dutasteride, and bromhexine should be initiated as early as possible once a positive test of the virus is established as currently investigated in several clinical trials of camostat in COVID-19.¹⁰³⁻¹⁰⁶ We hypothesize that the clinical outcome would be significantly improved if the drugs are administered early. The elastase inhibitors AAT and sivelestat should be administered only to hospitalized patients who suffer from a progressive disease and pronounced dyspnea. We encourage that these agents are to be administered—as stated above—together with camostat or dutasteride once patients are admitted to the hospital and continued throughout the hospitalization period to provide adequate prophylaxis against COVID-19 respiratory complications particularly ARDS.^{46,47,49} We also emphasize here that such antiprotease treatment should always be tested as an add-on therapy to available antiviral drugs and not as replacement since it is vital to target the virus both directly and indirectly to achieve the best clinical outcome possible.

It is very important to point out that several antiviral drugs that are currently being tested against SARS-CoV-2 have not shown significant clinical benefit in COVID-19 patients. There are at least four published randomized controlled trials evaluating the effectiveness of the RNA polymerase inhibitor remdesivir in treating COVID-19 patients.¹⁰⁷⁻¹¹⁰ These trials reported mixed findings with no clear mortality benefits. Wang et al in their randomized controlled trial found that remdesivir did not significantly improve the time to clinical improvement although this time interval was numerically shorter in patients treated with remdesivir within 10 days of symptom onset compared to those treated with placebo.¹⁰⁷ Beigel et al in their randomized controlled trial reported an overall shorter recovery time among patients in the remdesivir group compared to those in the placebo group regardless of disease severity.¹⁰⁸ Goldman et al in their randomized phase III trial comparing a 5-day course with a 10-day standard course of remdesivir reported no significant differences in both groups after adjustment of imbalances in baseline clinical status.¹⁰⁹ Spinner et al also examined the effectiveness of a 5-day and a 10-day remdesivir course, compared with standard care at day 11 after treatment initiation in a randomized phase III trial involving hospitalized patients with moderate COVID-19.¹¹⁰ The authors found that patients who received remdesivir for 5 days had significantly higher odds of better clinical status distribution compared to those who received standard care. Although the FDA has approved remdesivir for COVID-19 treatment, the current evidence is insufficient to support its use as a first-line therapy against COVID-19. Regarding the safety and efficacy

of the viral protease inhibitors lopinavir-ritonavir in COVID-19 patients, there are at least six published randomized controlled trials.¹¹¹⁻¹¹⁶ Most of the trials are of small sample size and show either no benefit or only a mild reduction in time to symptoms resolution with low certainty.¹¹⁷ A recent large-sized trial showed that lopinavir-ritonavir combination has no significant effect on the 28-day mortality, duration of hospital stay, risk of progression to invasive mechanical ventilation or death.¹¹⁵ Consequently, the evidence available so far does not support the use of lopinavir-ritonavir combination for treating hospitalized COVID-19 patients. Taken together, the results of all these clinical trials of antiviral drugs clearly emphasize the need for alternative approaches to treat SARS-CoV-2 infections. One such approach discussed extensively in this review is targeting host cell protease enzymes, which we believe is worth exploring.

6 | CONCLUSION AND OUTLOOK

In summary, we emphasize the importance of host cell proteases as potential drug targets for the treatment of SARS-CoV-2 infection and highlight therapeutic mechanisms that have not been sufficiently exploited to impair the virus capacity to spread through its host cells. We present a collection of clinically approved drugs as well as drugs under investigation that either suppress the transcription of proteases or increase the expression of their natural protease inhibitors. We also include drugs that are reported to possess protease inhibitory activity. These are believed to be potential candidates for drug repurposing and immediate preclinical testing in cell line models to verify their efficacy. As many of these candidates have been in clinical use for several years and their safety profiles are well established, we encourage their rapid clinical testing in patients with COVID-19 in combination with antiviral drugs. This would constitute a two-hit approach where not only viral proteins/enzymes necessary for viral replication are targeted but also the host cell machinery that the virus takes advantage of to facilitate its propagation in its infected host.

7 | Nomenclature of Targets and Ligands

Key protein targets and ligands in this article are hyperlinked to corresponding entries in <http://www.guidetopharmacology.org>, the common portal for data from the IUPHAR/BPS Guide to PHARMACOLOGY,¹¹⁸ and are permanently archived in the Concise Guide to PHARMACOLOGY 2019/20.¹¹⁹

DISCLOSURE

None.

AUTHOR CONTRIBUTIONS

IAS and MMAM conceptualized the idea in consultation with MAH. IAS and MMAM reviewed literature and wrote the initial draft. MAH and SSH critically reviewed the initial draft and expanded certain sections of the review. All authors contributed to revising the

manuscript in view of reviewers' comments. All authors have read and approved the final version for publication.
