Highlights

Atlantic salmon primary hepatocytes were used to screen for interaction effects caused by PAHs and pesticides.

Lipidomic and transcriptomic profiling suggested perturbation of lipid metabolism and endocrine disruption.

The pesticides gave the strongest responses, despite having less effect on cell viability than the PAHs.

The primary mixture effect was additive.

At high concentrations, the pesticides acted synergistic by decreasing cell viability and downregulating CYP3A and FABP4.

13 Abstract

14

Increasing use of plant feed ingredients may introduce contaminants not previously associated 15 with farming of salmonids, such as pesticides and PAHs from environmental sources or from 16 17 thermal processing of oil seeds. To screen for interaction effects of contaminants newly 18 introduced in salmon feeds, Atlantic salmon primary hepatocytes were used. The xCELLigence cytotoxicity system was used to select optimal dosages of the PAHs 19 benzo(a)pyrene and phenanthrene, the pesticides chlorpyrifos and endosulfan, and 20 combinations of these. NMR and MS metabolic profiling and microarray transcriptomic 21 profiling was used to identify novel biomarkers. Lipidomic and transcriptomic profiling 22 suggested perturbation of lipid metabolism, as well as endocrine disruption. The pesticides 23 gave the strongest responses, despite having less effect on cell viability than the PAHs. Only 24 25 weak molecular responses were detected in PAH-exposed hepatocytes. Chlorpyrifos suppressed the synthesis of unsaturated fatty acids. Endosulfan affected steroid hormone 26 synthesis, while benzo(a)pyrene disturbed vitamin D3 metabolism. The primary mixture 27 28 effect was additive, although at high concentrations the pesticides acted in a synergistic 29 fashion to decrease cell viability and down-regulate CYP3A and FABP4 transcription. This work highlights the usefulness of 'omics techniques and multivariate data analysis to 30 31 investigate interactions within mixtures of contaminants with different modes of action.

39 **1. Introduction**

40

41 Marine fish oils was traditionally the main source of the persistent organic environmental pollutants (POPs) in salmon feed and farmed Atlantic salmon (Salmo salar L.) (Berntssen et 42 al., 2010). Replacing marine ingredients with plant ingredients has reduced the levels of these 43 traditional POPs in salmon feeds, but as a consequence introduced a new cocktail of plant-oil 44 derived contaminants, such as polycyclic aromatic hydrocarbons (PAHs) and pesticides, that 45 have not previously been associated with farming of salmonids (Berntssen et al., 2010; Glover 46 47 et al., 2007). The introduction of these contaminants to salmon feeds has led to concerns about potential effects on fish health, including interactions with nutritional pathways. Plant 48 oils may be contaminated with PAH during the thermal processing of the oil seeds or 49 indirectly from environmental sources, such as exhaust gases from traffic or from atmospheric 50 particles deposited on the crops during growth (Fromberg et al., 2007; SCF, 2002). The 51 combustion process of oil seeds cause a predominant increase in 2-3 ring PAHs (e.g. 52 53 phenanthrene), while 4-5 ring PAHs (e.g. benzo(a)pyrene) are present to a lesser extent in the plant crude oils (Teixeira et al., 2007; Dennis et al., 1991). In a feeding trial, a 36% increase 54 of phenanthrene was detected in the fillets of Atlantic salmon fed alternative plant feed (3.2 55 μ g kg⁻¹ or 0.018 μ M) compared to fish fed traditional marine fish feed (2.4 μ g kg⁻¹ or 0.013 56 µM). In addition, the levels of benzo(a)pyrene increased from not being detected in the 57 traditional Atlantic salmon fillets to low concentrations being detected (0.3 μ g kg⁻¹ or 0.0012 58 μM) in the plant fed fish fillets (Berntssen et al., 2010). The acute toxicity of PAH in exposed 59 rainbow trout (Oncorhynchus mykiss) and largemouth bass (Micropterus salmonides) is 60 known to increase with increasing number of aromatic rings (Black et al., 1983). 61 62 Phenanthrene is therefore considered to have a relatively low toxicity. Phenanthrene is a noncvtochrome P450 1A (CYP1A)-inducing PAH, with aryl hydrocarbon receptor (AhR) 63 64 independent toxicity (Pathiratne and Hemachandra, 2010; Johnson et al., 2008), while the 4-5 ring PAHs have an AhR dependent mode of action. The main toxicological effects of PAHs, 65 66 however, are in their genotoxicity and potential endocrine disruption in teleosts (Donnelly and 67 Naufal, 2010; van der Oost et al., 2003; Johnson et al., 2008). Suppressed steroid levels and 68 steroid synthesis inhibition (Monteiro et al., 2000; Seruto et al., 2005; Yan et al., 2012) have been detected in PAH-exposed teleosts as well as retinoid signalling disruption (Benisek et 69 al., 2011). 70

72 Endosulfan and chlorpyrifos are pesticides used on crops, and residue levels have been 73 reported in products from plants such as soya or maize (Jergentz et al., 2005; Marchis et al., 74 2012) that are commonly used as ingredients in salmon feeds (Berntssen et al., 2007). In 75 2011, the concentration range measured in farmed Atlantic salmon were 0.2-5.8 μ g/kg $(0.0005-0.014 \ \mu\text{M})$ of α -endosulfan and $0.2-1.2 \ \mu\text{g/kg}$ $(0.0005-0.003 \ \mu\text{M})$ of β -endosulfan 76 77 (NIFES, 2014) while chlorpyrifos-methyl has recently been detected in salmon feed (Nácher-78 Mestre et al., 2014). These pesticides act as endocrine disruptors (Krøvel et al., 2010; 79 Grünfeld and Bonefeld-Jorgensen, 2004). Disturbed steroid production and steroid 80 biosynthesis (Angelis et al., 2009; Viswanath et al., 2010) as well as histopathological 81 changes have been reported in a variety of fish species exposed to chlorpyrifos (Deb and Das, 82 2012). Adverse effects like liver metabolic perturbations (Ashad et al., 2007; Glover et al., 83 2007; Krøvel et al., 2000) and disturbed lipid metabolism such as steatosis have been detected 84 in endosulfan exposed Atlantic salmon in vitro and in vivo (Krøvel et al., 2010; Glover et al., 85 2007). Elevated ethoxyresorufin O-deethylase activity (EROD) has been observed in endosulfan exposed Atlantic salmon in vivo (Glover et al., 2007). 86

87

In vitro models are useful supplements to animal models for the evaluation of underlying 88 89 mechanisms of drugs and contaminants, and for interaction studies (Bouhifd et al., 2012; Xia 90 et al., 2008; Judson et al., 2010; Walum et al., 2005; Søfteland et al, 2011). To ensure optimal 91 non-cytotoxic exposure concentrations for in vitro assessments, cell viability and dose-92 response curves of well-known transcriptional markers are often evaluated (ISO, 2009; 93 Judson et al., 2010; Søfteland et al., 2011). The xCELLigence system use impedance-based, continuous real-time assessment of cytotoxicity and mode of action, and is especially suitable 94 95 to determine when, and at which concentration, to collect cells for downstream analyses (Xia et al., 2008; Atienzar et al., 2011; Judson et al., 2010; Walum et al., 2005). The xCELLigence 96 97 system has an equal, or even higher, cytotoxicity sensitivity than the standardised methods 98 certified by ISO (Atienzar et al., 2011; Ceriotti et al., 2007) and has been used in large-scale 99 screening of toxicants (Judson et al., 2010; Xia et al., 2008). In feed safety evaluations, a 100 contaminant-by-contaminant approach has traditionally been applied in the risk assessment. 101 This approach may however be inappropriate in animals exposed to a cocktail of contaminants (Bandele et al., 2012; Kortenkamp and Altenburger, 2011). A toxicological 102 103 effect of a mixture can be greater (synergistic interaction) or lesser (antagonistic interaction) 104 than expected, and these outcomes are often difficult to predict. This is especially true when 105 mixtures are composed of contaminants with differing modes of action and knowledge

regarding such contaminant mixtures effects is in general lacking (Kortenkamp andAltenburger, 2011).

To gain toxicological knowledge about contaminants found in elevated levels in novel plant-based salmon feeds, the aim of this in vitro study was to screen for interaction effects using metabolomic, lipidomic and transcriptomic profiling. To ensure we used non-cytotoxic exposure concentrations, and to find the most potent mixture concentrations, the xCELLigence system was applied for cytotoxicity assessment. RT-qPCR gene expression analysis of well-known and new biomarkers were used for contaminant dose-response determination and interaction evaluation. Atlantic salmon primary hepatocytes were selected as an experimental model.

131 **2.** Materials and Methods

132

133 2.1 Chemicals

(6,7,8,9,10-hexachloro-1,5,5a,6,9,9,a-hexahydro-6,9-metano-2,4,3-benza-Endosulfan 134 dioxathiepin-3-oxide, $\alpha + \beta \sim 2 + 1$; PESTANAL[®], analytical standard), chlorpyrifos (O.O-135 diethyl-O-3,5,6-trichlor-2-pyridyl phosphorothioate, PESTANAL[®], analytical standard), 136 phenanthrene ($\geq 98\%$ pure) and benzo(a)pyrene ($\geq 96\%$ pure) were all purchased from Sigma-137 Aldrich (Oslo, Norway). Dimethyl sulfoxide (DMSO) stock solution was purchased from 138 Scientific and Chemical Supplies Ltd. (Bilston, UK), chloroform (HPLC grade) was 139 purchased from Fisher Scientific (Loughborough, UK) and ammonium acetate was purchased 140 141 from Sigma-Aldrich Co. Ltd (Dorset, UK).

142

143 2.2 Isolation of primary cultures of hepatocytes

144 Juvenile Atlantic salmon (Salmo salar L.) were obtained and kept at the animal holding facility at the Institute of Marine Research, Bergen, Norway at Havbruksstasjonen, Matre. 145 146 The fish were fed once daily with a special feed produced without addition of synthetic antioxidants and with low levels of contaminants, supplied by EWOS, Norway (Harmony 147 148 Nature Transfer 75). Feed concentrations of chlorpyrifos, endosulfan, benzo(a)pyrene and phenanthrene were all under the level of quantification. All glassware, instruments and solutions 149 were autoclaved prior to liver perfusion. Hepatocytes were isolated from 8 Atlantic salmon 150 151 (325-515g) with a two-step perfusion method previously described in Søfteland et al. (2009). The final cell pellet was resuspended in L-15 medium containing 10% fish serum (FS) from 152 salmon (Nordic BioSite, Oslo, Norway), 1% glutamax (Invitrogen, Norway) and 1% 153 154 penicillin-streptomycin-amphotericin (10000 units/ml potassium penicillin, 10000 µg/ml 155 steptomycin sulfate and 25 µg/ml amphotericin B.) (Lonzo, Medprobe, Oslo, Norway). The 156 Trypan Blue exclusion method, performed in accordance with the manufacturer's protocol 157 (Lonzo), was used to determine cell viability. The different cell suspensions used in this study had cell viability between 83-94%. The cell suspensions were plated on 2 µg/cm² laminin 158 (Sigma-Aldrich, Oslo, Norway) coated culture plates (TPP, Trasadingen, Switzerland), and 159 the hepatocytes were kept at 10° C in a sterile incubator without additional O₂/CO₂ (Sanyo, 160 CFC FREE, Etten Leur, Netherland). The following cell concentrations were used; 7.2×10^6 161

162 cells per well in 6-well plates (in 3 ml complete L-15 medium), 2.6×10^6 cells per well in 12-

well plates (in 2 ml complete L-15 medium), 0.2×10^6 cells per well in xCELLigence 96-well

164 plates (in 0.2 ml complete L-15 medium).

165

166 *2.3 Chemical exposure*

The primary cells were cultured for 36-40 hrs prior to chemical exposure with a change of 167 168 medium (containing 10% FS) after 18-20 hrs. The cells were exposed for 24 hrs to single contaminants, i.e. endosulfan, phenanthrene and benzo(a)pyrene (0.01, 0.1, 1, 10, 100 µM). 169 chlorpyrifos (0.1, 1, 10, 100, 1000 μ M) or to simple mixtures of endosulfan, phenanthrene, 170 benzo(a)pyrene and chlorpyrifos according to a factorial experimental design. A full factorial 171 design was used with low (1 µM) and high (100 µM) concentrations, a zero (0.4% DMSO 172 173 control) concentration, and one centre point (50.5 μ M) in order to evaluate linearity (Table 1). 174 The concentrations used for the factorial design were determined from the cell viability and 175 RT-qPCR dose-response curves (Fig. 1-5). 1 µM was chosen as the low concentration for all contaminants due to the up-regulation observed for CYP1A and CYP3A at this concentration 176 by benzo(a)pyrene, endosulfan and chlorpyrifos, in addition to that 1 μ M was the lowest 177 concentration that gave a significant cell viability reduction for phenanthrene. The high (100 178 179 µM) concentration was chosen since all contaminants, except chlorpyrifos gave a significant cell viability reduction at this concentration and since all contaminants significantly up-180 181 regulated vitellogenin (VTG) and/or fatty acid binding protein 4 (FABP4) at this concentration. Cells from three fish were used for cell viability and RT-qPCR dose-response 182 curves evaluation in a preliminary experiment. In a second experiment cell viability, RT-183 aPCR, metabolomics, lipidomics and microarray analysis were used to evaluate cells 184 185 toxicological response when exposed to individual contaminants, accordingly to a full 186 factorial design (Table 1) or to selected contaminant mixtures from the design. Cells from five additional fish were employed. The exposure medium contained 1% FS. The exposure 187 188 medium was substituted with new medium after 18-20 hrs and the chemical exposure was 189 sustained for another 24 hrs. The lowest concentration (0.01 µM) used in the dose-response 190 curves with endosulfan and phenanthrene corresponds to actual levels measured in Atlantic salmon fillets (Berntssen et al., 2010; NIFES, 2014). 191

193 2.4 Cytotoxicity testing of chemicals

194 For the cytotoxicity assessment of the four chemical compounds, real time impedance data 195 obtained by the xCELLigence systems (Roche Diagnostics, Oslo, Norway) was used. The 196 xCELLigence system quantifies electrical impedance across electrodes in 96-well cell culture E-Plates. The impedance measurement gives quantitative information regarding cells' 197 198 biological status including morphology, cell number and viability. Optimal plate coating conditions and cell density were determined in preliminary experiments (data not shown). 199 200 After a background reading was measured, the appropriate number of cells was added to the plate. The cells were allowed to attach at room temperature (30 min) before the plate was 201 202 placed on the xCELLigence plate reader in the cell incubator for continuous impedance 203 recording. The real time cell monitoring was conducted at 10°C in an incubator without 204 additional O₂/CO₂ (Sanyo, CFC FREE, Etten Leur, Netherland), using the RTCA single plate xCELLigence platform. The data was collected with intervals of 2 min after contaminant 205 206 exposure for 12 hrs, then every 15 min for 120 h. The cell index (CI) is a parameter that is 207 derived from the measured cell-electrode impedance data that quantifies the status of the cells 208 (Abassi et al. 2009). Generally, when cells attach onto the electrodes, the CI value increases. A decrease in CI correlates to cell detachment. However, changes in cell morphology will 209 affect the CI. A normalized CI (NCI) at a specific time point is calculated by dividing the CI 210 at that particular time by the CI of a reference time point which is set to 1. The last time point 211 before compound exposure was used for the normalization, allowing a more precise 212 213 comparison of the control versus effect of the different contaminant concentrations tested. The 214 CI values presented here were calculated from three or five replicate values. Determination of 215 cytotoxic effects was done according to the International standardised test for in vitro 216 cytotoxicity, ISO 10993-5:2009 (ISO, 2009). Contaminant will be deemed cytotoxic when cells viability exceeds 30% reduction compared to the control. 217

218

219 2.5 Metabolomics and lipidomics

220 2.5.1 Metabolite extraction and NMR spectroscopy

Lyophilized samples were extracted using a 1145 μ l mixture of chloroform:methanol:water (2:2:1.8) and vortexed in 2 ml glass vials. The polar and non-polar phases of this bi-phasic mixture were separated, and the polar phase (500 μ l) was vacuum centrifuged (30 min at

224 300K), frozen and freeze dried, for Nuclear magnetic resonance spectroscopy (NMR) 225 analysis. For the non-polar phase, 300 μ l were evaporated under N₂ and stored at -80°C 226 before shipment on dry ice for MS analysis.

Subsequently the dried polar metabolite fraction was resuspended in 200 µl D₂O with 1 mM 227 TMSP and transferred to NMR tubes. All samples were maintained at 277 K and analyzed 228 229 within 48 hrs of resuspension. NMR was performed on a Bruker DRU 600 NMR spectrometer 230 (600.23 MHz for ¹H) fitted with a 5 mm CPQCI cryogenic probe (Bruker Corporation). Three 231 mm NMR tubes were used with the Bruker Sampletrack autosampler in which the samples were kept at 279 K before (and after) analysis. The spectra were recorded at 300 K with 232 233 suppression of the residual water resonance using the noesygppr1d pulse sequence from the Bruker pulse sequence library. A pulse width of 7.91 µs was used to collect 128 free induction 234 decays with 32K data points with a spectral window of 12,019 Hz (20 ppm). The acquisition 235 time was 2.73 s and the interscan delay was 3 s. The noesy mixing time was 10 ms. The data 236 were zero filled to 64K and exponential line broadening of 0.3 Hz applied before Fourier 237 238 transformation. The spectra were phased and baseline corrected.

239

240 2.5.2 FT-ICR mass spectrometry

All dried lipid samples were resuspended in an equal volume of 2:1 methanol:chloroform with 241 242 5 mM ammonium acetate. Lipidomic analyses were conducted in negative ion mode using a hybrid 7-T FT-ICR mass spectrometer (LTQ FT Ultra, Thermo Fisher Scientific, Bremen, 243 244 Germany) with a chip-based direct infusion nanoelectrospray ionisation assembly (Triversa, 245 Advion Biosciences, Ithaca, NY). Nanoelectrospray conditions comprised of a 200 nL/min flow rate, 0.4 psi backing pressure and -1.2 kV electrospray voltage controlled by ChipSoft 246 247 software (version 8.1.0). Mass spectrometry conditions included an automatic gain control setting of 5 x 10⁵ and a mass resolution of 100,000. Analysis time was 4.25 min (per technical 248 249 replicate), controlled using Xcalibur software (version 2.0, Thermo Fisher Scientific). Spectra were collected using the "SIM stitching" method, i.e. acquisition of fourteen overlapping 250 251 selected ion monitoring (SIM) mass ranges that were subsequently fused together, ranging from m/z 70 to 2000 (Southam et al., 2007, Weber et al., 2011). Each sample was analysed in 252 253 triplicate. A quality control (QC) sample consisting of a pooled aliquot of the samples was 254 analysed repeatedly throughout the batch of samples.

255

256 2.6 Microarray and Quantitative real-time RT-PCR

257 2.6.1 RNA extraction

The RNeasy Plus mini kit (Qiagen, Crawley, UK) was used to extract total RNA according to 258 259 the manufacturer's protocol. RNA was eluted in 30 µl RNase-free MilliQ H₂O and stored at -260 80°C. The RNA quantity and quality were assessed with the NanoDrop® ND-1000 UV-Vis 261 Spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA) and the Agilent 2100 262 Bioanalyzer (Agilent Technologies, Palo Alto, CA, USA) pursuant to the manufacturer's 263 instructions. The integrity of the RNA was evaluated with the RNA 6000 Nano LabChip® kit (Agilent Technologies). The samples used in this experiment had 260/280nm absorbance 264 265 ratios that varied between 1.76 and 2.41, 260/230 nm ratios above 2 and RNA integrity number (RIN) values above 9.5, which indicate pure RNA and intact samples (Schroeder et 266 al., 2006). 267

268

269 2.6.2 Microarray; target synthesis and microarray hybridization

For experimental samples, anti-sense amino-allyl RNA (aaRNA) was amplified from the 270 original individual column-cleaned total RNA samples using the Message Amp II aRNA 271 Amplification kit (Ambion, Life Technologies, Burlington, ON), following the manufacturer's 272 273 instructions. Only one round of amplification was necessary and it was carried out with 1 µg of total RNA input. For the common reference, an equal contribution of every sample 274 275 involved in the experiment was pooled and 1 µg of this pool was used in four amplification 276 reactions. The resulting amplified aaRNA from each reaction was pooled to make a final 277 common reference. Amplified aaRNA quality and quantity was measured using UV 278 spectrophotometry and agarose gel electrophoresis, respectively. Anti-sense amino-allyl RNA 279 was labelled with either Cy3 or Cy5 (GE Healthcare, Mississauga, ON) following the 280 manufacturer's instructions with minor modifications. Twenty µg of amplified aaRNA was 281 precipitated overnight following standard molecular biology procedures and re-suspended in coupling buffer (Ambion, Life Technologies); the resulting solution was used in the labelling 282 283 reaction following the manufacturer's protocol. Experimental individuals were labelled with Cy5 and the common reference was labelled with Cy3. Labelled aaRNA was purified using 284

the columns supplied with the kit, and labelling efficiency was measured using the"microarray" function of the NanoDrop (ThermoFisher, Mississauga, ON).

287

Agilent 4-by-44,000 oligonucleotide probes (4x44K) custom salmonid microarrays designed 288 289 by the consortium for Genomic Research in All Salmonids Project (cGRASP) (Jantzen et al., 2011) were used in this experiment (GEO accession # GPL11299). Hybridizations were 290 291 carried out following the manufacturer's instructions using 825 ng of each labelled sample 292 (i.e. one experimental sample and one reference sample) per array and the HI-RPM 293 hybridization buffer (Agilent, Mississauga, ON). Hybridizations were carried out for 16 hrs at 65°C with 10 rpm rotation in an Agilent hybridization oven. Following hybridizations, arrays 294 were washed following the manufacturer's instructions. Arrays were scanned using a Perkin 295 Elmer ScanArray Gx Plus at 5 µm resolution and laser power at 90%. If the average signal 296 intensity between channels was not within 300 photomultiplier tube settings (PMTs) were 297 298 adjusted to balance the channel in subsequent scans. Fluorescence intensity data was extracted from TIFF image files using Imagene v8.5 (BioDiscovery, El Segundo, CA). 299

300

301 2.6.3 Quantitative real-time RT-PCR

The transcriptional levels of selected target genes were quantified with a two-step real-time 302 reverse transcription polymerase chain reaction (RT-PCR) protocol. A serial dilution curve of 303 total RNA with six points in triplicates between 1000 - 31 ng were made for PCR efficiency 304 305 calculations. 500 ng of total RNA was added to the reaction for each sample, and reverse transcription (RT) reactions were run in duplicates using 96-well reaction plates. No-template 306 307 control (ntc) and no-amplification control (nac) reactions were run for quality assessment for 308 every gene assay. The 50 µl RT reactions were performed at 48°C for 60 min utilizing a 309 GeneAmp PCR 9700 thermocycler (Applied Biosystems, Foster City, CA, USA). Individual 310 RT reactions contained 1X TaqMan RT buffer (10X), 5.5 mM MgCl₂, 500 mM dNTP (of 311 each), oligo dT primers (2.5 µM), 0.4 U/µl RNase inhibitor and 1.67 U/µl Multiscribe Reverse 312 Transcriptase (Applied Biosystems) and RNase-free water.

For every gene analysed, quantitative real-time RT-PCR (real-time qPCR) was run in 10 ul 314 315 reactions on a LightCycler® 480 Real-Time PCR System (Roche Applied Sciences, Basel, 316 Switzerland) containing 2.0 µl cDNA (diluted twofold). The real-time qPCR was carried out in two 384-well reaction plates using SYBR Green Master Mix (LightCycler 480 SYBR 317 Green master mix kit, Roche Applied Sciences, Basel, Switzerland) containing gene-specific 318 319 primers and FastStart DNA polymerase. PCR runs were performed with a 5 min activation and denaturing step at 95°C, followed by 45 cycles with each cycle consisting a 10 s 320 denaturing step at 95°C, a 10 s annealing step and finally a 10 s extension step at 72°C. The 321 322 primer pairs had an annealing temperature of 60°C; see Table 2 for primer sequences, amplicon sizes and GenBank accession numbers. Final primer concentrations of 500 nM were 323 used. For confirmation of amplification of gene-specific products, a melting curve analysis 324 was carried out and the second derivative maximum method (Tellmann, 2006) was used to 325 326 determine crossing point (CT) values using the Lightcycler 480 Software. To calculate the 327 mean normalized expression (MNE) of the target genes, the geNorm VBA applet for Microsoft Excel version 3.4 was used to calculate a normalization factor based on three 328 reference genes. By using gene-specific efficiencies calculated from the standard curves, the 329 330 CT values are converted into quantities (Vandesompele et al., 2002). Elongation factor 1 AB (EF1AB) and acidic ribosomal protein (ARP) and β -actin were the selected reference genes 331 332 for this experiment. The reference genes were stable with gene expression stability (M) values of 0.38. 333

334

335 2.7 Data analysis

336 2.7.1 Metabolomics

The processed NMR spectra were imported into Matlab (The Mathworks, Inc.) using Prometab v3.3 software (Viant et al. 2003). The region from 10 to 0.5 ppm was imported with a resolution of 0.02 ppm which resulted in 4750 data points, and transformed using a generalized log transformation. Principal Component Analysis (PCA) and Partial Least Squares Discriminant Analysis (PLS-DA) was performed in PLS-toolbox v7.0.1 (Eigenvector Research, Inc.) on normalized and mean centered data prior to multivariate statistical analyses.

344

345 *2.7.2 Lipidomics*

All analyses were performed in Matlab 7.8.0 with PCA and PLS-DA analysis performed in 346 347 PLS-toolbox v.6.7.1. Mass spectra were processed using a three-stage filtering algorithm as 348 described in Payne et al. (2009). Samples were subsequently normalised using probabilistic 349 quotient normalisation (Dieterle et al., 2006). Processing the raw mass spectra yielded a dataset that was further optimised using a QC based method as described in Kirwan and 350 351 Broadhurst et al. (2013). Mass features with over 20% missing values across all samples were removed and the resulting intensity matrix was submitted for univariate statistical analysis as 352 353 described below. A k-nearest neighbour approach (Hrydziuszko et al 2012) was applied to 354 impute missing values to the same dataset and it was transformed using a generalized log 355 transformation prior to multivariate statistical analysis. The final lipidomics dataset was 356 comprised of 1603 mass features upon which statistical analyses were conducted. PCA and 357 PLSDA were performed to assess the overall effect (http://CRAN-R-project.org). All 358 supervised models were validated using cross validation and permutation testing to avoid 359 over-fitting. Univariate statistical analyses were conducted on the lipidomics dataset. An 360 analysis of variance (ANOVA) followed by Games-Howell (GH) post hoc testing (Games and Howell 1976) was applied across the control and the highest doses of each of the four 361 362 contaminants using a custom adapted version of freely available Matlab scripts (Trujillo-Ortiz 363 and Hernandez-Walls 2003). ANOVA and GH post hoc testing was also applied across all 364 doses of the contaminant mixtures against control. ANOVA was also applied to compare the control against the low and high doses for each individual contaminant. A Benjamini-365 Hochberg false discovery correction of 10% was applied to all univariate statistical results 366 (Benjamini and Hochberg 1995). 367

368

Lipidomic pathway analysis was conducted according to Kanehisa (2008) utilising pathways listed in the Kyoto Encyclopedia of Genes and Genomes (KEGG) database. For each mass feature, KEGG and MI-Pack software were used to assign a putative empirical formula(e) and identity based on accurate mass. To measure the perturbation of each pathway, the empirical formulae associated with the significantly changing mass features were compared against the total number of detected empirical formulae in that pathway to give a "percent of empirical formulae perturbed" for each treatment.

- 376
- 377

378 2.7.2 Microarray data pre-processing and analysis

379 Data pre-processing and normalization were carried out in R using the mArray package. Print-380 tip Loess normalization (i.e. per sub-grid), threshold setting and removal of low-381 quality/flagged spots were done as described in Booman et al. (2011) and Hori et al. (2012). 382 After spot quality filtering, features absent in more than 30% of the arrays were discarded and not used in the analysis, resulting in a final list of 9469 probes. Missing data for the 9469 383 probes was imputed using LSImpute (Bo et al., 2004; Celton et al., 2010) as previously 384 described (Hori et al., 2012). Differentially expressed genes between controls and exposed 385 groups were identified using the rank products algorithm (Breitling et al., 2004) as 386 implemented in the RankProd (Hong et al., 2006) R package with a percentage of false 387 positives (PFP) of 10%. A Rank Product test is demonstrated to be a robust method for 388 microarray experimental designs with few replicates (Jeffery et al, 2006). 389

390

391 2.7.3 xCELLigence and RT-qPCR data

GraphPad Prism 6.0 software (GraphPad Software Inc., Palo Alto, CA, USA) was used for the 392 393 statistical analyses of the xCELLigence and the RT-qPCR dose-response curves evaluation 394 using one-way ANOVA followed by a Dunnett's post hoc test (p < 0.05) to detect treatment variation in contaminant-exposed hepatocytes. Mean±SE were calculated for three or five 395 replicates. For the statistical analyses of the VTG RT-qPCR dose-response curve, Student's t-396 test (p < 0.05) was used to detect significant difference between the highest chlorpyrifos 397 the 0.4% DMSO control hepatocyte cell cultures. Regression was 398 concentration and 399 performed with PLS (Wold et al., 1984) to correlate the design matrix to the responses of 400 different transcripts. Modde 9.0 (Umetrics, Umeå, Sweden) was used for the experimental 401 design and the PLS analysis. Before the PLS analysis the blend matrix was augmented with 402 interaction terms, the data were scaled to unit variance and mean centred. The PLS models 403 were validated with respect to explained variance and goodness of prediction (shown as Q^2), obtained after cross validation (Wold, 1978). The PLS model was in addition evaluated with 404 405 respect to goodness of fit (\mathbb{R}^2) .

415	
416	3.1Cytotoxicity screening and RT-qPCR biomarker screening
417	3.1.1 Individual exposures
418	3.1.1.1 Cytotoxicity screening
419	Primary Atlantic salmon hepatocytes were used to establish cytotoxic dose-response curves
420	for the two individual PAHs benzo(a)pyrene and phenanthrene, and for the two individual
421	pesticides chlorpyrifos and endosulfan. With the xCELLigence cytotoxicity system,
422	phenanthrene (Fig. 1A) was the most potent compound, significantly decreased cell viability
423	of 21%, 25%, and 22% at the three highest exposure concentrations (1-100 μ M) respectively.
424	Cell viability was only significantly reduced at the highest exposure concentrations (100 μ M)
425	for benzo(a)pyrene with 25% (Fig. 1B) and endosulfan (Fig. 1C) 24% compared to the 0.4%
426	DMSO control. None of the applied chlorpyrifos concentrations (0.1-1000 μ M) induced a
427	significant cell viability reduction effects in the hepatocytes (Fig. 1D). No significant
428	difference was found between the medium control and the 0.4% DMSO control, and therefore
429	the medium control was not included in Fig. 1A-1D.
430	

431 3.1.1.2 RT-qPCR biomarker screening

To ensure we were working in a relevant concentration range for Atlantic salmon primary hepatocytes, dose-response curves were established for the four selected biomarkers CYP1A, CYP3A, VTG and FABP4. Chlorpyrifos (Fig. 2) gave a bell-shaped CYP1A transcript upregulation pattern, though CYP1A was only significantly up-regulated at 10 μ M with a fold change (FC) of 16.8 (p=0.001). The CYP3A transcript did not show a clear dose-response however CYP3A was significantly elevated at 0.1 (p=0.01) and 10 μ M (p=0.5) of chlorpyrifos. The FABP4 transcript was significantly expressed at 100 μ M chlorpyrifos

(p=0.0001) compared to the control. In similarity to FABP4, the VTG transcript was 439 440 according to the microarray results (data not shown) significantly induced at the highest 441 chlorpyrifos exposure concentration (100 μ M) compared to the control. The ANOVA posthoc 442 analysis of the RT-qPCR data did however not confirm this finding, even though a direct comparison between the control and the 100 μ M group using the t-test suggested this 443 difference was significant (VTG, p=0.05). Endosulfan exposure (Fig. 3) gave significant up-444 regulation of FABP4 (p=0.05) and VTG (p=0.0001) at a concentration of 100 μ M, with the 445 VTG transcript showing the highest up-regulations with a FC of 17.3. Benzo(a)pyrene (Fig. 4) 446 447 up-regulated CYP1A transcription (p=0.0001), most profoundly at 1 μ M (FC of 191), with a significant dose-dependent reduction in the expression levels at concentrations of 10 and 100 448 μ M. As for the CYP1A transcript, CYP3A was only significantly up-regulated by 449 450 benzo(a)pyrene at 1 μ M (p=0.001). In addition, benzo(a)pyrene significantly up-regulated 451 VTG at 100 μ M (p=0.05). No distinct dose-dependent responses were detected in hepatocytes 452 exposed to phenanthrene (Fig. 5), however, the transcripts CYP1A (p=0.05) and VTG 453 (p=0.001) were significantly induced at the highest concentration (100 μ M) investigated. 454 VTG had the highest induction with a FC of 10.9 compared to the control.

455

Based on the cell viability data obtained with the xCELLigence system and transcriptional dose-response curves obtained with RT-qPCR, a factorial design with non-cytotoxic concentrations of the contaminants, 1 μ M (low) and 100 μ M (high), were subsequently used in the cytotoxicity mixture toxicity interaction evaluation. The different contaminant mixtures used in the factorial design are presented in Table1.

461

462 *3.1.2. Mixture exposures*

463 *3.1.2.1 Cell viability screening*

The different contaminant mixtures gave at the most a cell viability reduction of 12% compared to the control, and contaminant mixture 4 and 16 showed the strongest cell viability reduction effect. PLS analysis was performed on the xCELLigence normalized cell index (NCI) values obtained for mixture exposures to benzo(a)pyrene, phenanthrene, chlorpyrifos and endosulfan according to a factorial design. The PLS model (R^2 -value = 0.7 and the Q^2 value 0.4.) had four negative linear terms for benzo(a)pyrene, phenanthrene, chlorpyrifos and

470 endosulfan, indicating that all chemicals contributed to reduced cell viability, however only 471 two linear terms, for phenanthrene (p=0.029) and endosulfan (p=0.015), were significant (Fig. 472 6). The model also contained one negative interaction term, for chlorpyrifos and endosulfan 473 which were significant (p=0.031). A contour analysis of the xCELLigence cytotoxicity PLS model indicated a synergistic interaction response between chlorpyrifos and endosulfan in 474 475 mixture-exposed hepatocytes.

476 3.2. Metabolic profiling

Cells exposed to DMSO (0.4%), 1 µM (low dose) and 100 µM (high dose) of chlorpyrifos, 477 endosulfan, phenanthrene, and benzo(a)pyrene, and contaminant mixtures 1 (1µM of all 478 contaminants), 4 (100 μ M of the PAHs and 1 μ M of the pesticides) and 16 (100 μ M of all 479 contaminants) were selected to be analysed with metabolomics (water-soluble metabolites) 480 MAR 481 and lipidomics (N=5).

482

483 3.2.1 Lipidomics

484 3.2.1.1 Individual exposures

Unsupervised PCA and supervised PLS-DA data analysis of the lipidomics spectra revealed 485 an apparent separation of the exposed group from the control only at the highest dose (100 486 μ M) of the two concentrations analysed for chlorpyrifos (p=0.007; Fig. 7A and 7B), 487 488 endosulfan (p=0.014; Fig. 7C and 7D), and benzo(a)pyrene (p=0.005; Fig. 7E and 7F). PCA 489 also demonstrated a separation between the control samples and lowest dose of endosulfan. 490 The ANOVA followed by GH post hoc analysis of the high dose exposures of the individual 491 contaminants revealed that chlorpyrifos induced the greatest number of significantly changing 492 mass features with 92 mass features significantly changing compared to the control. 493 Endosulfan induced the second largest perturbation with 22 significant mass features, 494 followed by benzo(a)pyrene (7 significant mass features). Phenanthrene has been removed 495 from the analysis as it induced only one significant perturbation compared to the control. Fig. 496 8A characterises the overlap of the significant mass features across the individual contaminant 497 exposure. Benzo(a)pyrene shared no significant mass features with chlorpyrifos and 498 endosulfan, whereas the pesticides had 6 significant mass features in common, making the 499 pesticides more similar in their mode of action.

500

501 The KEGG pathway analysis (Table 3) of the individual contaminants revealed 10 potentially 502 perturbed pathways, five of which are linked to fatty acid and cholesterol metabolism. 503 Chlorpyrifos may have an affect on the biosynthesis of unsaturated fatty acids (suppressed 504 several desaturase pathways, e.g. $\Delta 9$ and $\Delta 11$ desaturases) (Fig. 9A), linoleic acid metabolism 505 (suppressed desaturase and elongase pathways to produce ARA, as well as increased cytochrom P450 pathway eicosanoid production) (Fig. 9B) and arachidonic acids metabolism 506 507 (increased eicosanoid production) (Fig. 9C). Endosulfan indicates an affect on primary bile acid biosynthesis and steroid biosynthesis (increased levels of cholesterol for steroid hormone 508 509 biosynthesis and production of VTG) (Fig. 9D) while benzo(a)pyrene mainly appears to affect 510 steroid biosynthesis (affecting vitamin D metabolism, increased levels of vitamin D 511 metabolites) (Fig. 9D).

512

513 *3.2.1.2 Mixture exposures*

The contaminant mixtures induced a higher number of significantly changing mass features 514 515 (q<0.1 by ANOVA, p<0.05 by GH), than the individual contaminants except chlorpyrifos. They 516 primarily affected mass features with putative identities that have been linked to the pathways 517 of bile acid biosynthesis and biosynthesis of unsaturated fatty acids. Contaminant mixture 16 518 induced most changes with 149 significant mass features compared to contaminant mixture 1 with 57 significant mass features and contaminant mixture 4, the least effective inducer, with 519 520 39 significant mass features (Fig. 8B). However, when modelling by PLS-DA, only 521 contaminant mixture 4 (p=0.031) and contaminant mixture 16 (p=0.002) could be reliably 522 distinguished from the other classes.

2

523

When comparing the overlap between the significant mass features induced by the high dose of individual contaminants and those induced by the contaminant mixtures, 40% of the mass features induced by the individual contaminants were found to overlap with those induced by the contaminant mixtures (Fig. 8C). When comparing the different contaminant mixtures, 70% of significantly changing mass features were uniquely significantly changed with respect to the control only in contaminant mixture 16 which contained the highest doses of all four contaminants. Despite this, none of the features significant in the comparison of the control

class and mixture 16 were significantly different in more than two of the individual 531 contaminant classes when compared to mixture 16 suggesting that the combination of 532 contaminants caused an additive effect (Table SI1). According to the KEGG pathway 533 analysis, contaminant mixture 16 may affect other pathways not perturbed by the other 534 mixtures but the coverage of these pathways was poor and thus the significance of these 535 perturbations are uncertain. According to the KEGG pathway analysis, contaminant mixtures 536 537 (Table 3) affected primary bile acid biosynthesis, suppressed biosynthesis of unsaturated fatty acids (Fig. 9 A) and linoleic acid metabolism (Fig. 9B) and steroid biosynthesis (increased 538 539 levels of cholesterol for steroid hormone biosynthesis and production of VTG) (Fig. 9D).

540

541 3.2.2 Metabolomic (water-soluble metabolites)

The PCA and PLS-DA analyses of the polar metabolites showed no significant differencesbetween the control and exposed groups (data not presented).

544

545 *3.3 Transcriptomic*

546 *3.3.1 Mixture exposures*

547 3.3.1.1 Microarray analysis

548 In addition to the lipidomic and metabolomic screening, microarray was used for 549 identification of new biomarkers. Contaminant mixture 4 was used for the microarray experiment since it showed the strongest cell viability reduction of the different contaminant 550 551 mixtures in the cytotoxicity screening. Top rank product lists of differentially expressed features with PFP below 10% in Atlantic salmon hepatocytes exposed to contaminant mixture 552 553 4 (N=5), are presented in Table 4. In total 17 features were significantly regulated with PFP 554 below 10%, all significantly affected features like microtubule-associated proteins 1A/1B 555 light chain 3B precursor (MAP1LC3B), transcription factor SOX-4 (SOX4) and VTG were 556 up-regulated, and VTG (C065R146) showed the strongest response with a FC of 13.19.

557

558 3.3.1.2 RT-qPCR Contaminants interaction evaluation of mixtures

PLS analysis was performed on seven transcripts (Table 5) and the expression levels (MNE) obtained in cells exposed to benzo(a)pyrene, phenanthrene, endosulfan and chlorpyrifos using a factorial design in order to determine possible chemical interactions. VTG, MAP1LC3B, SOX4 were chosen as biomarkers due to their expression levels identified with microarray screening, whereas CYP1A, CYP3A, FABP4, and peroxisome proliferator-activated receptor α (PPAR α) were all target genes evaluated with RT-qPCR that were not identified with the microarray screening.

566 The PLS analysis of three transcripts showed no combined effect between the contaminants in the mixture suggesting that only one of the contaminants was driving the observed response. 567 568 For example, endosulfan (p=0.025) was the only contaminant contributing to VTG upregulation ($R^2=0.658$ and $O^2=0.47$), despite the fact that the PAHs and the pesticides' singly 569 570 induced VTG and that the PLS model contained one negative interaction term for chlorpyrifos and endosulfan (p=0.02). The PLS analysis showed that, of the three transcripts that revealed 571 additivity, CYP1A ($R^2 = 0.93$ and the $Q^2 = 0.81$) gave the strongest response. However, of the 572 four contaminants only chlorpyrifos (p=0.0001) and endosulfan (p=0.0001) contributed to the 573 additive transcriptional reduction of CYP1A expression levels. The FABP4 (R²=0.95 and 574 $Q^2=0.66$) was another transcript where additivity was identified and benzo(a)pyrene (p=0.01), 575 phenanthrene (p=0.034) and chlorpyrifos (p=0.00007) all contributed to this additivity. 576 Chlorpyrifos had the largest regression coefficient, and thus had a larger contribution to 577 positive regulation of FABP4. Further, the model had three significant negative interaction 578 579 terms. A counterplot of the interaction term between phenanthrene and endosulfan (p=0.022) showed antagonistic interaction at low concentrations. However, the interaction term for 580 581 chlorpyrifos and endosulfan (p=0.0003) had the largest regression coefficient, and thus had a 582 larger contribution to the regulation of FABP4. The counterplot analysis of this interaction term identified a synergistic interaction between chlorpyrifos and endosulfan on the up-583 584 regulation of FABP4 at high concentrations, with increasing phenanthrene concentrations. The PLS model for CYP3A ($R^2=0.83$ and $Q^2=0.49$), the second transcripts for which 585 synergistic interactions were identified, had only two significant terms, one negative linear 586 term for endosulfan (p=0.0005) and one negative interaction term for endosulfan and 587 588 chlorpyrifos (p=0.042). A counterplot analysis of the negative interaction term showed a 589 synergistic interaction between the two pesticides on the reduction of CYP3A at high concentration and with increased concentration of phenanthrene. 590

594

595 **3. Discussion**

Cytotoxicity assays are extensively used to assess *in vitro* cell viability in fish cell cultures, 596 597 including to rank chemical toxicity and to evaluate chemical mixtures (Segner and Braunbeck, 2003; Wood et al., 2006). According to the international standard for *in vitro* cytotoxicity 598 testing (ISO, 2009), contaminants are first considered cytotoxic when cell viability are 599 reduced with more than 30%. The four compounds assessed with the xCELLigence system 600 showed only a 0-25% cell viability reduction, therefore, none of the contaminants were 601 602 cytotoxic in the concentration ranges used in this study. Phenanthrene was the most potent compound, significantly decreasing cell viability with 21-25% at the three highest 603 604 concentrations (1, 10 and 100 μ M). This result is in line with a study of Shirmer et al. (1998) 605 who, in exposed rainbow trout gill cells (RTgill-W1), found that five lighter PAHs with two or three benzene rings, including phenanthrene, gave a stronger cell viability reduction than 606 607 heavier PAHs such as the five ringed PAH benzo(a)pyrene. Shirmer et al. (1998) suggested 608 that the lipid solubility of heavier PAHs prevents them from being adequately accumulated in cells and membranes. In zebrafish (Danio rerio) larvae, phenanthrene and benzo(a)pyrene 609 610 exposure caused a similar toxic response (Wolinska et al., 2011), suggesting that lighter PAHs 611 can be at least as potent as heavier PAHs.

612

Similar to benzo(a)pyrene, the endosulfan xCELLigence screening revealed a dose-dependent 613 614 reduction of cell viability, which was significant only at the highest exposure concentration (100 μ M). This result is in line with previous findings obtained with the MTT cell viability 615 616 test (0.01-100 μ M) in endosulfan-exposed Atlantic salmon primary hepatocytes (Krøvel et al., 617 2010). Compared to endosulfan, none of the applied chlorpyrifos concentrations (0.1-1000 618 μ M) affected cell viability in the exposed hepatocytes. In a cytotoxicity screening with the 619 rainbow trout liver (RTL-W1) and rainbow trout gonadal (RTG-2) cell lines, Babin and 620 Tarazona (2005) found chlorpyrifos (0-8.6 μ M) to be the most potent compound of six pesticides tested in a neutral red assay and a FRAME KB protein assay. The reason for this 621 discrepancy in sensitivity between salmonid primary hepatocytes and cell lines to chlorpyrifos 622 623 is not known.

624

625 Lipidomic and transcriptomics profiling were further employed to generate hypotheses about 626 the potential modes of action of the studied contaminant and contaminant mixtures. The 627 contaminant exposure showed that chlorpyrifos had the most dominant effect on the lipodome 628 despite showing no effect on cell viability. Endosulfan induced the second largest 629 perturbation, followed by benzo(a)pyrene, while phenanthrene, the most potent cell viability reducing contaminant, induced no distinct perturbation according to the lipidomics data. 630 Chlorpyrifos appeared to affect pathways associated with linoleic acid metabolism as well as 631 the biosynthesis of unsaturated fatty acids, whereas endosulfan may affect steroid 632 633 biosynthesis and primary bile acid biosynthesis pathways. Lipids have important 634 physiological functions in fish, such as structural components in cell membranes, in cell 635 signalling, and in storage of cellular energy (Torstensen et al., 2001). Therefore, the downregulation of the biosynthesis of unsaturated fatty acids suggests that chlorpyrifos, among 636 637 other pathways, may disturb energy-requiring metabolic mechanisms (LeBlanc et al., 2012). Inhibition of essential linolenic fatty acid metabolism has previously been seen in 638 norflurazon-exposed rat liver cells (Hagve et al., 1985). Earlier studies have shown impaired 639 fatty acid metabolism (Ortiz-Zarragoitia and Cajaraville, 2005) as well as metabolic 640 perturbation by exposure to pesticides like endosulfan and chlorpyrifos (Demur et al., 2013; 641 Wang et al., 2011) and to PAHs (Van Scoy et al., 2010; Lin et al., 2009) in exposed mammals 642 643 and salmonids.

644

645 Although eicosanoids can be difficult to detect since they are normally present at low 646 concentrations in biological samples, several putatively annotated eicosanoids in different 647 lipid metabolism pathways was affected by chlorpyrifos exposure in Atlantic salmon hepatocytes. In the arachidonic acid metabolic pathway the putatively annotated eicosanoid 648 649 tromboxan (11-dehydro-TXB2), was one of several elevated in the chlorpyrifos exposed 650 primary hepatocytes. 11-dehydro-TXB2 is an intermediate of TXA2, which is a vasoconstrictive eicosanoid that has previously been associated with liver injury (Yokayama 651 652 et al., 2005). In the linoleic acid metabolism pathway, the putatively annotated eicosanoids 653 9,12-dihydroxy-epoxyoctadecanoate, a precursor of tetrahydrofurandiols (THF-diols), and 654 TriHOME were elevated by chlorpyrifos exposure. These metabolites are involved in 655 inflammatory reactions, cellular energy metabolism and cell homeostasis (Mickalik and Wahli, 2008; Penigrahy et al., 2010). THF-diols are eicosanoids that are involved in 656

657 inflammatory reactions and are produced by cytochrome P-450 epoxidations and epoxide 658 hydrolase (sEH) mediated hydrolysis (Konkel and Schunck, 2011; Moghaddam et al., 1996). 659 Several CYP enzymes like CYP1A1/2 and CYP3A4 take part in linoleic acid cytochrome P450 eicosanoid biosynthesis in mammalian species (Konkel and Schunck, 2011). According 660 to the RT-qPCR data, both CYP1A (17-fold up-regulated) and CYP3A (1.46-fold up-661 regulated) transcripts were induced in hepatocytes exposed to chlorpyrifos. A similar CYP-662 663 induction was not seen in endosulfan-exposed hepatocytes in this study or in an earlier study 664 by Krøvel et al., (2010). CYP1A and CYP3A, via AhR- and PXR-receptor activation 665 respectively, could therefore be responsible for the biotransformation of chlorpyrifos and the fatty acids and the production of lipid THF-diols (Konkel and Schunck, 2011). 666

667

The fatty acid binding proteins (FABPs) have an essential role in the regulation of the flux of 668 669 fatty acid in cells, and FABP4 is a well-established marker for inflammation and metabolic 670 syndrome in humans (Cabre et al., 2007; Terra et al., 2011). The putatively identified FABP 671 that may represent the adipose tissue type FABP (h6FABP or FABP11) in fish, an orthologue to mammalian FABP4 (Torstensen et al., 2009), was induced by both pesticides; with 672 673 chlorpyrifos being the most potent inducer according to the RT-qPCR data. Endosulfan has 674 previously been shown to cause lipid metabolism disturbances such as steatosis, which is 675 triacylglycerols (TAG) accumulation in liver, in both in vitro [i.e. in exposed hepatocyte cultures (Krøvel et al., 2010)] and *in vivo* studies (Glover et al., 2007) involving Atlantic 676 salmon. FABP4 was significantly elevated by endosulfan at 100 μ M, the same concentration 677 678 at which Krøvel et al., (2010) detected accumulation of TAG in endosulfan exposed primary 679 hepatocytes. In humans trophoblasts, increased lipid accumulation was found to be linked to elevated transcription of FABP4 (Duttaroy, 2009; Scifres et al., 2011). FABP4 is 680 transcriptionally activated by the peroxisome proliferator activated receptor γ (PPAR γ) 681 682 (Michalik and Wahli, 2008), which is the key regulator of adipogenesis (Janesick and 683 Blumberg, 2011). Our results therefore suggest that PPARs may be upstream regulators of the 684 response to chlorpyrifos and endosulfan in exposed hepatocytes, explaining the observed 685 effects on eicosanoid lipids and steroids, which is in line with earlier published results 686 (Michalik and Wahli, 2008; Li and Chiang, 2009; Parkinson and Ogilvie, 2008; Peraza et al., 2006). 687

688

In pesticide and contaminant mixture exposed cells the lipidomics data revealed that the levels of cholesterol, the precursor of steroid hormone biosynthesis, were higher than in the other

691 exposure groups. An effect on steroid hormone biosynthesis was also suggested by the 692 observed induction of a transcript encoding VTG, the primary egg-yolk precursor protein, by 693 the contaminant mixtures and both pesticides at 100 μ M. Endosulfan was the strongest 694 inducer of VTG according to the RT-qPCR data. VTG is normally produced in female fish under estrogenic stimulation of ovarian follicle development (Ekman et al., 2008; Hinton et 695 al., 2008). A number of studies have shown endocrine disruption effects caused by 696 organochlorine and organophosphate pesticides, both possessing the ability to interfere with 697 the estrogen receptor (ER) pathway (Krøvel et al., 2010; Grünfeld and Bonefeld-Jorgensen, 698 699 2004). The lipid metabolism perturbations induced by endosulfan and chlorpyrifos in male 700 hepatocytes can in part be linked to endocrine disruption due to an increased need for cholesterol for VTG production. Comparable effects have been detected in fish exposed to 701 702 estrogenic compounds. Earlier fish trials have shown impaired fatty acid metabolism (Ortiz-703 Zarragoitia and Cajaraville, 2005) and/or effects on cholesterol homeostasis (Bravo et al. 704 1999; Erickson et al. 1989) by dioxin (Fletcher et al., 2005; Moran et al., 2004) and estrogen 705 exposure (Ekman et al., 2008), as well as metabolic perturbation by exposure to pesticides 706 like endosulfan and chlorpyrifos (Demur et al., 2013; Wang et al., 2011).

707

The lipidomics data suggested that PAHs, similar to the pesticides and the contaminant 708 709 mixtures, perturbed steroid biosynthesis by elevating several cholesterol intermediates, and 710 thereby affecting steroid hormone biosynthesis. In benzo(a)pyrene and contaminant mixture 711 exposed cells, higher vitamin D3 levels (putatively identified) were detected when compared 712 to the other exposure groups. Given that fish can only acquire D3 vitamin via its feed, a timedependent reduction of vitamin D3 levels owing to cells metabolism of the vitamin, suggests 713 714 that vitamin D3 steroid biosynthesis has been inhibited by these contaminants (Lock et al., 715 2010). Potent CYP1A inducers, like benzo(a)pyrene, have previously been reported to down-716 regulate or inhibit estrogen receptor signalling (Kortenkamp, 2007; Yan et al., 2012). 717 However at the highest concentration of $benzo(a)pyren (100 \ \mu M)$, VTG was significantly 718 induced, as shown for chlorpyrifos, which also appears to be a potent CYP1A inducer.

719

Despite phenanthrene's lack of lipidomic perturbation and effect on CYP3A expression levels, the RT-qPCR analysis revealed that phenanthrene significantly elevated CYP1A at the highest exposure concentration (100 μ M), indicating that it is a weak CYP1A inducer. Surprisingly, phenanthrene toxicity in fish therefore appears to be induced via the AhR as

724 compared to earlier findings in mammals where phenanthrene toxicity has been found to be 725 independent of the AhR induction (Pathiratne and Hemachandra, 2010; Johnson et al., 2008; 726 Wolinska et al., 2011). Weak CYP1A inducers have previously been found to act differently 727 in fish test systems possibly due to fish-specific CYP1A regulation (Søfteland et al., 2011) with fish having more AhRs then mammals (Hahn and Hestermann, 2008), in addition to low 728 CYP2K/CYP2M and CYP3A induction abilities. In addition, VTG was highly elevated in 729 cells exposed to 100 μ M of phenanthrene, with a FC of 10.9. A similar VTG response was not 730 detected in corresponding studies with zebrafish or medaka (Horng et al., 2009; Wolinska et 731 732 al., 2011). However, hydroxylated PAHs like 2-hydroxyphenanthrene, which have structural similarities to E2, have been shown to possess estrogenic activity in estrogen-sensitive 733 reporter gene assays (ER-CALUX) (Wenger et al., 2009). 734

735

According to the lipidomics data, additivity appeared to be the dominant mixture effect 736 737 between the PAHs and the pesticides. The high level of overlap in lipidome perturbation between the individual contaminants and contaminant mixtures, and the increased number of 738 739 perturbations induced by contaminant mixtures with high levels of pesticides, indicate that the 740 majority of changes in the lipidome induced by the contaminant mixtures represent the sum of 741 the individual contaminants. However, some synergistic activity between the compounds 742 cannot be ruled out. In line with earlier studies with potent CYP1A inducers (van den Berg et al., 2006) and EDCs (Kortenkamp, 2007), the PLS interaction evaluation of the CYP1A and 743 FABP4 transcriptional data, confirmed that additivity was the dominant mixture effect caused 744 745 by the PAHs and pesticides. However, at high concentrations, synergistic interaction effects 746 were detected. In the contaminant mixture cell viability screening, at high concentrations 747 chlorpyrifos synergistically interacted with and potentiated endosulfan's cytotoxic response, 748 despite having no effect on cell viability alone. A similar synergistic effect on cell viability 749 reduction has previously been shown in Ehrlich ascites tumour cells from Swiss albino mice, 750 in which Thiram, at non-cytotoxic concentration, was found to potentiate the cell viability 751 reduction of endosulfan (Rana and Shivanandappa, 2010). In line with the cell viability 752 results, at high concentrations a synergistic effect between endosulfan and chlorpyrifos was 753 detected on the transcriptional down-regulation of CYP3A and FABP4. A similar additive (at 754 low concentrations) and synergistic response (at high exposure concentration) was reported in 755 an acetylcholinesterase activity inhibition study with juvenile coho salmon (Oncorhynchus 756 *kisutch*) exposed to a mixture composed of organophosphate and carbamate pesticides (Laetz

757 et al., 2009). A synergistic inhibition of cholinesterase has also been detected in great 758 ramshorns (Planorbarius corneus) exposed to a binary mixture of chlorpyrifos and one 759 organophosphate pesticide (Cacciatore et al., 2012). The mechanism behind the pesticides' synergistic effect on the down-regulation of CYP3A and FABP4 is, however, not known. 760 CYP3A is an important contaminant biotransformation enzyme in addition to having a role in 761 the metabolism of steroid hormones like testosterone (Kretschmer et al., 2005) and other 762 lipids. The observed down-regulation of this transcript may therefore affect CYP3A-763 dependent biotransformation of contaminants and turnover of hormones and lipids in cells. 764 765 This illustrates that risk assessment based on toxicological data from single-contaminant exposure studies can underestimate the impact of the mixture of new contaminants with 766 different modes of action, like PAHs and pesticides, which may be introduced to farmed 767 Atlantic salmon from feeds with high inclusion levels of vegetable oil. 768

769

770

772

771 **5. Conclusions**

Despite that the two PAHs benzo(a)pyrene and phenanthrene were associated with higher cell 773 viability reduction potential the two pesticides endosulfan and chlorpyrifos caused the greatest 774 775 lipidomics and transcriptomic perturbations. According to the lipidomics data, the two metabolic pathways most strongly affected by chlorpyrifos and endosulfan, contaminants that 776 777 could be introduced in novel salmon feeds from plant-based ingredients, were fatty acid and 778 steroid biosynthesis. These responses were to some extent confirmed by the transcriptomic data, which showed that biomarkers linked to endocrine disruption and lipid metabolism were 779 780 affected. According to the current observations, the interaction effects between the contaminants could mostly be explained as an additive effect, however at high concentrations 781 782 the contaminants acted in a synergistic manner.

1285 **Highlights**

- Atlantic salmon primary hepatocytes were used to screen for interaction effects caused by 1286
- 1287 PAHs and pesticides.
- Lipidomic and transcriptomic profiling suggested perturbation of lipid metabolism and 1288 endocrine disruption. 1289
- The pesticides gave the strongest responses, despite having less effect on cell viability than 1290 the PAHs. 1291
- The primary mixture effect was additive. 1292
- 1293 At high concentrations, the pesticides acted synergistic by decreasing cell viability and downregulating CYP3A and FABP4. 1294
- 1295
- 1296
- 1297

these as putatively annotated empirical formulae onto metabolic pathways as listed by KEGG (http://www.genome.jp/kegg/). The percentage perturbation of the pathway can then be estimated based on the percentage of the original pathway detected that was Table 3: Table of metabolic pathways perturbed by exposing salmon hepatocyte cells to contaminants. The extent of perturbation was measured by collating the mass features for each contaminant that had changed significantly compared to the control and mapping significantly different. Figures in red denote the greatest perturbation seen in that pathway for the individual contaminants.

Table 4: Top rank product list of differently expressed features with PFP below 10% in Atlantic salmon hepatocytes exposed to contaminant mixture 4^{a} (N=5).

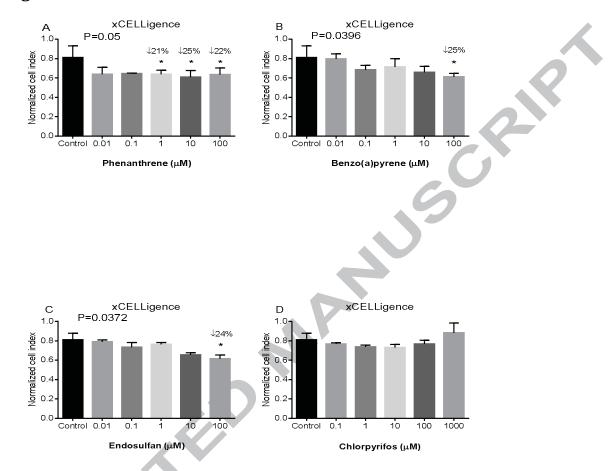

^aContaminant mixture 4 is composed of benzo(a)pyrene and phenanthrene (100 μM), endosulfan and chlorpyrifos (1 μM).

Table 5: Scaled and centered PLS regression coefficient models for different genes measured in primary Atlantic salmon hepatocytes exposed to chlorpyrifos (Chl), endosulfan (End), benzo(a)pyrene (Ben) and phenanthrene (Phe) using mean normalized expression (MNE) and factorial design. The combined effects identified with contour plot analysis for the different models are presented in the response column. The specific contaminants that contributed to a particular combined effect like additivity, synergism or antagonism are specified in parentheses behind the identified combined response in the response column. PLS plots of genes where only one contaminant was responsible for the observed response is indicated in the response column by naming the contaminant responsible for the effect.

Figures

Fig. 1: Dose-response curves for Normalized cell index (NCI) values obtained for primary Atlantic salmon hepatocytes (N=3) exposed to (A) phenanthrene (B) benzo(a)pyrene, (C) endosulfan, (D) and chlorpyrifos. The values represent the mean \pm SE of three replicates (N=3). The analyses showed significant difference between the control (DMSO 0.4%) and the exposed group indicated by * (p=0.05).

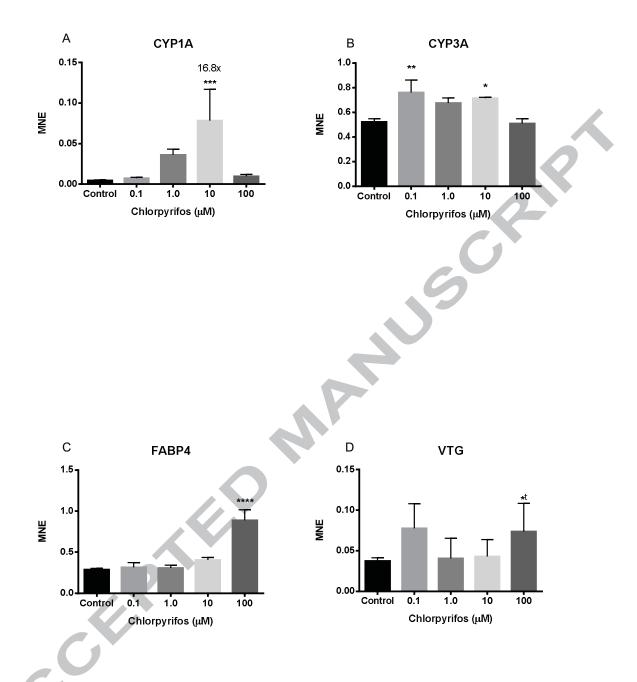

Fig. 2: Dose-response curves for A) CYP1A, B) CYP3A, C) FABP4, D) VTG, using normalized expression (MNE) values, obtained for primary Atlantic salmon hepatocytes exposed to chlorpyrifos and the DMSO control (0.4%). The values represent the mean \pm SE of three replicates (N=3). The ANOVA analyses showed significant difference between the control and the exposed group indicated by **** (P=0.0001), *** (p=0.01) and * (p=0.05). The Students't-test analyses showed significant difference between the control (DMSO 0.4%) and the exposed group indicated by *^t (p=0.05).

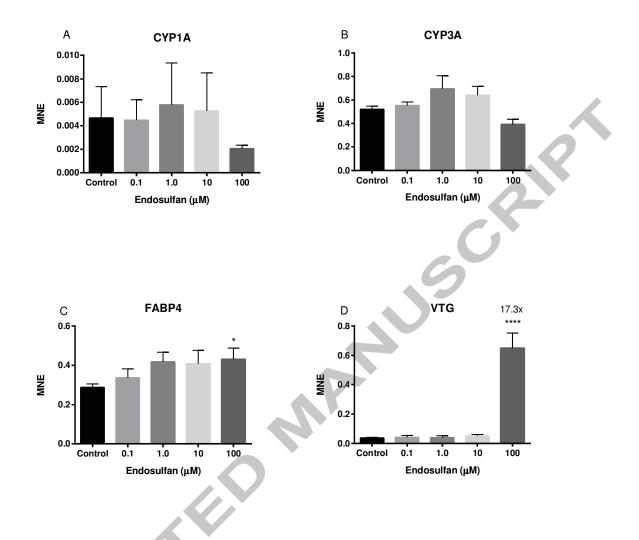

Fig. 3: Dose-response curves for A) CYP1A, B) CYP3A, C) FABP4, D) VTG, using normalized expression (MNE) values, obtained for primary Atlantic salmon hepatocytes exposed to endosulfan and the DMSO control (0.4%). The values represent the mean \pm SE of three replicates (N=3). The ANOVA analyses showed significant difference between the control and the exposed group indicated by **** (P=0.0001) and * (p=0.05).

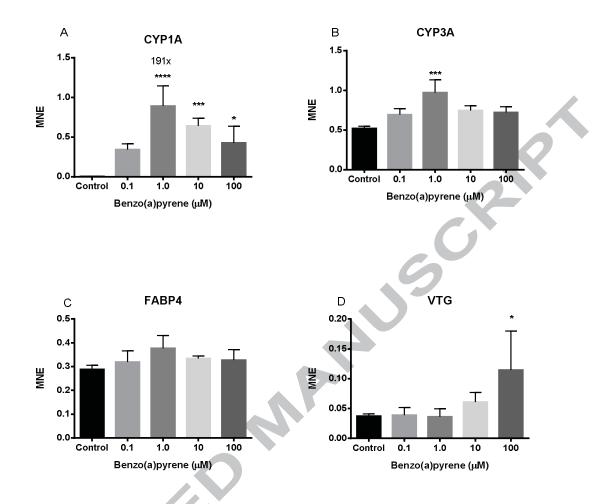

Fig. 4: Dose-response curves for A)CYP1A, B)CYP3A, C)FABP4, D) VTG, using normalized expression (MNE) values, obtained for primary Atlantic salmon hepatocytes exposed to benzo(a)pyrene and the DMSO control (0.4%). The values represent the mean \pm SE of three replicates (N=3). The ANOVA analyses showed significant difference between the control and the exposed group indicated by **** (P=0.001), *** (p=0.001) and * (p=0.05).

RCC

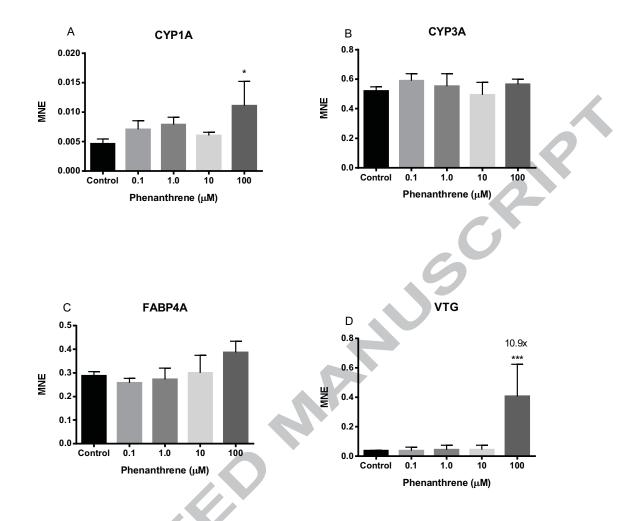

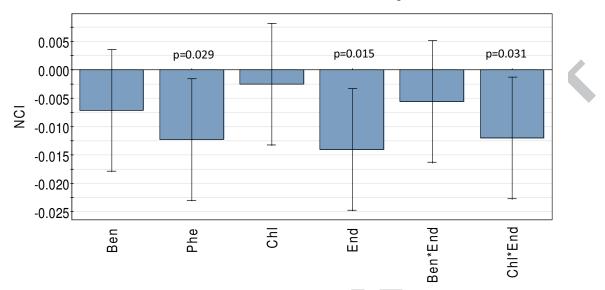

Fig. 5: Dose-response curves for A) CYP1A, B) CYP3A, C) FABP4 D) VTG, using normalized expression (MNE) values, obtained for primary Atlantic salmon hepatocytes exposed to phenanthrene and the DMSO control (0.4%). The values represent the mean \pm SE of three replicates (N=3). The ANOVA analyses showed significant difference between the control and the exposed group indicated by *** (p=0.001) and * (p=0.05).

ACC

Scaled & Centered Coefficients for xCELLigence

Fig. 6: Scaled and centered PLS regression coefficients with 95% confidence intervals for Normalized cell index (NCI) levels measured in primary Atlantic salmon hepatocytes exposed to benzo(a)pyrene, phenanthrene, chlorpyrifos and endosulfan accordingly to the factorial design (N=5). The model is based on 17 experimental objects, and had one PLS component. The model was good (R^2 =0.7 and Q^2 =0.4), containing four linear terms and two interaction terms.

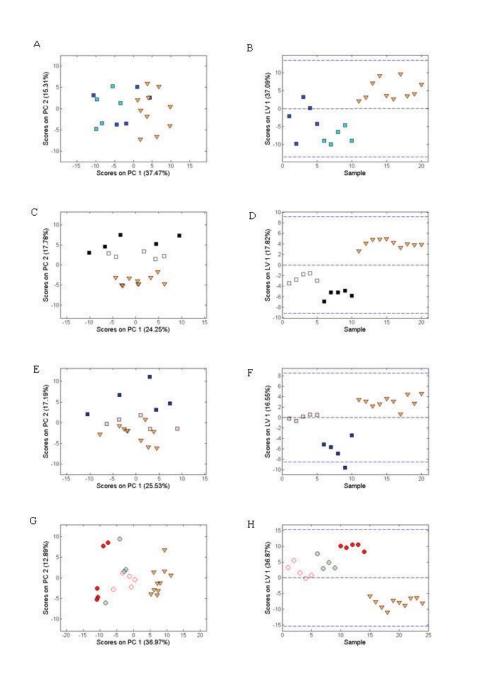

Fig. 7: PCA and PLSDA scores plots for lipidomics. PCA (left hand column) and PLSDA (right hand column) scores plots data from salmon hepatocyte cell cultures treated with chlorpyrifos (A and B), endosulfan (C and D), benzo(a)pyrene (E and F), or a mixture (I and J) of four contaminants (benzo(a)pyrene, chlorpyrifos, endosulfan and phenanthrene) at one of three different doses or DMSO control. One sample from the contaminant mixture 4 class has been removed as an outlier in the DIMS lipidomics data. Key to treatments: control(∇) low dose (1 µM) chlorpyrifos, (\blacksquare) high dose (100 µM) chlorpyrifos (\blacksquare), low dose endosulfan (\square), high dose endosulfan (\blacksquare), low dose benzo(a)pyrene

(), high dose bezo(a)pyrene () or mixtures 1 (), 4 () and 16 () of the four contaminants.

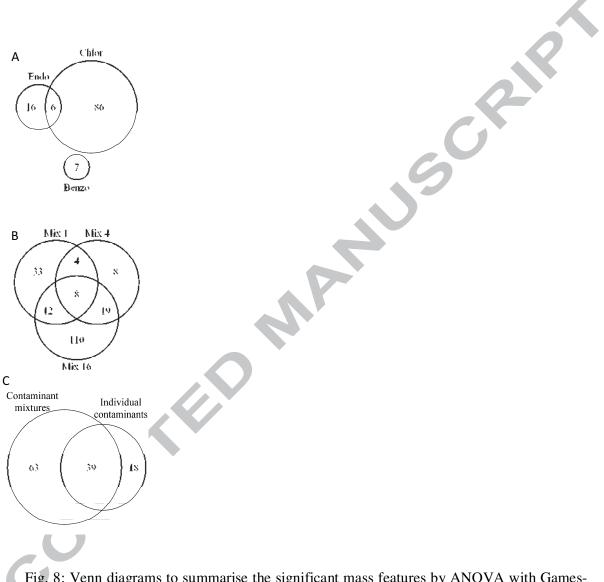

Fig. 8: Venn diagrams to summarise the significant mass features by ANOVA with Games-Howell post-hoc testing. The significant mass features between high dose individual contaminants versus control do not show much overlap (A). Phenanthrene was excluded from this analysis since statistical tests revealed there was only one mass feature significantly different from the control after FDR correction. This mass feature was also significantly different in endosulfan compared to the control. (B) The Venn diagram displays the difference in significant mass features between different contaminant mixes and the control, and (C) displays the overlapping mass features that were significant in any individual contaminant and the contaminant mixes.

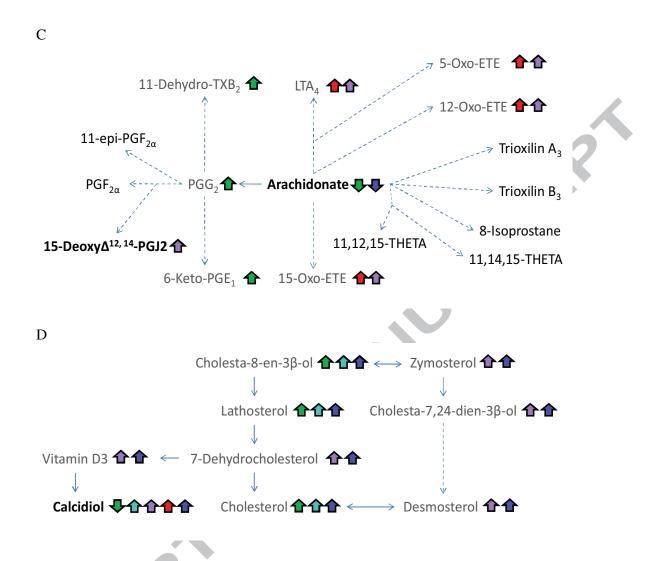

Fig. 9: Examples of metabolic pathways with significantly changing putatively annotated empirical formulae mapped onto them for each contaminant. All pathways have been reduced to show only the metabolites detected by direct infusion lipidomics. Block arrows demonstrate a significant fold increase or decrease following exposure to the contaminants in relation to the control group Key (\frown) chlorpyrifos (\frown) endosulfan (\frown) phenanthrene (\frown) benzo(a)pyrene (\frown) contaminant mixture. Dotted arrows represent two or more reactions between the metabolites of interest and metabolites in grey font indicate that potentially multiple metabolites of the same m/z exist in this pathway. Biosynthesis of unsaturated fatty acids pathway (A) and the linoleic pathway (B) shows perturbations only when chlorpyrifos or a contaminant mixture is used. By contrast, the arachidonic acid metabolism pathway (C) and the steroid pathway (D) (reduced to show only the section of interest) appear disrupted by a much greater range of contaminants.
