Spinal manipulation characteristics: a scoping literature review of force-time characteristics

Lindsay M Gorrell^{1*} , Luana Nyirö¹, Mégane Pasquier^{2,3}, Isabelle Page^{4,5}, Nicola R Heneghan⁶, Petra Schweinhardt¹ and Martin Descarreaux^{3,7}

Abstract

Background Spinal manipulation (SM) is a recommended and effective treatment for musculoskeletal disorders. Biomechanical (kinetic) parameters (e.g. preload/peak force, rate of force application and thrust duration) can be measured during SM, quantifying the intervention. Understanding these force-time characteristics is the first step towards identifying possible active ingredient/s responsible for the clinical effectiveness of SM. Few studies have quantified SM force-time characteristics and with considerable heterogeneity evident, interpretation of findings is difficult. The aim of this study was to synthesise the literature describing force-time characteristics of manual SM.

Methods This scoping literature review is reported following the Preferred Reporting Items for Scoping Reviews (PRISMA-ScR) statement. Databases were searched from inception to October 2022: MEDLINE (Ovid), Embase, CINAHL, ICL, PEDro and Cochrane Library. The following search terms and their derivatives were adapted for each platform: spine, spinal, manipulation, mobilization or mobilisation, musculoskeletal, chiropractic, osteopathy, physiotherapy, naprapathy, force, motor skill, biomechanics, dosage, dose-response, education, performance, psychomotor, back, neck, spine, thoracic, lumbar, pelvic, cervical and sacral. Data were extracted and reported descriptively for the following domains: general study characteristics, number of and characteristics of individuals who delivered/received SM, region treated, equipment used and force-time characteristics of SM.

Results Of 7,607 records identified, 66 (0.9%) fulfilled the eligibility criteria and were included in the analysis. Of these, SM was delivered to the cervical spine in 12 (18.2%), the thoracic spine in 40 (60.6%) and the lumbopelvic spine in 19 (28.8%) studies. In 6 (9.1%) studies, the spinal region was not specified. For SM applied to all spinal regions, force-time characteristics were: preload force (range: 0-671N); peak force (17-1213N); rate of force application (202-8700N/s); time to peak thrust force (12-938ms); and thrust duration (36-2876ms).

Conclusions Considerable variability in the reported kinetic force-time characteristics of SM exists. Some of this variability is likely due to differences in SM delivery (e.g. different clinicians) and the measurement equipment used to quantify force-time characteristics. However, improved reporting in certain key areas could facilitate more sophisticated syntheses of force-time characteristics data in the future. Such syntheses could provide the foundation upon which dose-response estimates regarding the clinical effectiveness of SM are made.

Keywords Spinal manipulation, Biomechanics, Force-time characteristics, Kinetics, Kinematics, Spine Pain

Introduction

The prevalence of musculoskeletal disorders, including low back and neck pain, is increasing globally [1, 2]. Based on age-standardized disability-adjusted life years, musculoskeletal disorders are currently ranked the 5th highest globally compared to a ranking of 10th in 1990 [3, 4]. In 2017, low back pain was the most prevalent musculoskeletal disorder globally (36.8%), with neck pain the third most prevalent (18.4%). These disorders are not only disabling but also costly, with low back and neck pain having the highest amount of health care spending by payor in the United States (US\$134.5 billion in 2016) [5]. Conservative treatments (e.g. spinal manipulation (SM)) are recommended and effective treatments for musculoskeletal disorders as part of multimodal therapy [6–9]. SM is characterized by a single high-velocity, low-amplitude (HVLA) thrust delivered to a joint with the intention of moving the articulation past its physiological range of motion but without exceeding its anatomic limit [10]. Force-time characteristics such as preload and peak force, rate of force application and thrust duration can be measured during the application of SM, allowing for biomechanical quantification of the intervention. Understanding these force-time characteristics is the first step towards identifying possible active ingredient/s responsible for the clinical effectiveness (e.g. decreased pain and increased range of motion (ROM) of the intervention). However, only a few studies quantify the delivery of SM and those that do, do so heterogeneously. Therefore, interpretation of reported results in this area is difficult. Highlighting this, to our best knowledge, there has been only one attempt to synthesise the literature reporting on the force-time characteristics of SM delivered to all regions of the spine [11]. In this 2010 systematic review, preload and peak forces delivered during SM were collated from 15 studies (cervical: $n=4$; thoracic: $n=8$; and lumbopelvic: $n=3$). Downie and colleagues concluded that heterogeneity in the included studies precluded a standardized biomechanical description of HVLA SM but that a relationship between preload, peak force and thrust duration was present. The authors recommended improved reporting of SM force-time characteristics when assessing the clinical efficacy of HVLA SM (e.g. in clinical trials). More recently, Gyer and colleagues performed a critical literature review of 20 studies (humans: $n=12$) in which SM was delivered to the thoracic ($n=5$), lumbar ($n=6$) or, both regions ($n=1$) [12]. While force-time characteristics of SM (e.g. thrust force and duration) were reported, the authors primarily investigated the relationship between force-time characteristics of SM and physiological and clinical outcomes. In summary, it was reported that there exists a dose-response relationship between force-time characteristics of SM and transient physiological outcomes (e.g. electromyographical

responses); however, it remains unknown what effect varying force-time characteristics of SM might have on clinical outcomes.

As such, improved reporting would provide a starting point for quantification of minimum thresholds (or dosages), for a range of force-time characteristics (e.g. thrust force and duration) and ultimately, for the determination of how these parameters affect the clinical effectiveness of SM. To date, such thresholds have been hypothesised but not systematically investigated [13, 14]. Indeed, similar findings were reported in an earlier scoping review on SM frequency and dosage effects on clinical and physiological outcomes which concluded that dosage effects clearly influence short-term physiological responses to manipulation but found no relationship between the force-time characteristics of SM delivery and clinical outcomes such as decreased pain and/or increased range of motion [15]. It is possible that heterogeneity in the literature (as reported by Downie and colleagues [11]) could be responsible for the observed lack of relationship between SM force-time characteristics and clinical outcomes. Additionally, the existence of a threshold above which the nervous system is sufficiently stimulated to realise a favourable clinical outcome could partially explain why clinical improvements have been reported in studies using different therapeutic approaches [16–18]. Therefore, the aim of this study was to synthesise the existing literature describing biomechanical (kinetic) parameters in the delivery of manual SM.

Methodology

This scoping literature review was conducted in 5 stages as outlined by Arksey and O'Malley [19]. Specifically: (i) the research question was identified; (ii) potentially relevant studies were identified; (iii) relevant studies were selected; (iv) data were charted; and (v) results were generated by collating, summarizing and reporting the data. The final step (optional consultation process) was not included as it was deemed to be unnecessary in the context of the current study. The Preferred Reporting Items for Scoping Reviews (PRISMA-ScR) statement was used to report the data [20]. The protocol was designed by an international, interprofessional team of chiropractors and physiotherapists with relevant methodological and clinical expertise and registered at the Open Science Framework Registry (<https://osf.io/3mqjs/>). Protocol deviations included that this study was originally designed (and the searches conducted) to capture information concerning the force-time characteristics of both SM and spinal mobilization (SMob). However, due to the large quantity of data published on this topic, it was decided to report the force-time characteristics of SM and SMob separately. Secondly, it was decided to exclude studies reporting on SM delivered to animals as it was unknown how

comparable (biomechanically) the delivery of the intervention was to SM delivered to humans.

Eligibility criteria

Eligibility criteria were selected by the research team using the Sample, Phenomenon of Interest, Design, Evaluation, Research Type (SPIDER) search concept tool [21].

Inclusion criteria

S – the sample population was humans (of any age) and inanimate objects (e.g. instrumented tool, manikin);

PI – the phenomenon of interest was manually delivered SM, delivered by any regulated health professional (e.g. chiropractor or physiotherapist) or student enrolled at an accredited institution;

D – observational study designs (e.g. case series studies, cohort and case-control studies);

E – kinetic variables of the intervention (e.g. force-time characteristics); and

R – original quantitative research data from studies utilizing SM as either the sole intervention or as a comparator.

Exclusion criteria

The following exclusion criteria were used: (i) SM and/or SMob delivered by a mechanical instrument or device; (ii) all other therapeutic modalities; (iii) manuscript not published in English, French or German; and (iv) studies that had been retracted, were secondary analyses, trial registrations, protocols, clinical practice guidelines, commentaries, editorials, conference proceedings or single case studies.

Search strategy

The following databases were searched from inception to 4 October 2022: MEDLINE(Ovid), Embase, CINAHL, ICL, PEDro and Cochrane Library. Reference lists of included studies were screened to insure all relevant literature was captured. The search strategy was informed by subject specific and methodological experts. The following search terms and derivatives were adapted for each search engine: (spine, spinal, manipulation, mobilization or mobilisation, musculoskeletal, chiropractic, osteopathy, physiotherapy, naprapathy, force, motor skill, biomechanics, dosage, dose-response, education, performance, psychomotor, back, neck, spine, thoracic, lumbar, pelvic, cervical and sacral). Search strategies for all databases are provided in Appendix 1.

Study selection process

Records retrieved from the electronic searches were exported to the Rayyan© online platform (2022) [22] and duplicate records were removed. Groups of two authors (LG and LN; LG and IP; LG and MP) independently

screened potentially eligible studies in a step-wise process, beginning with review of each title and abstract. Full-texts of the studies remaining after the first phase of screening were retrieved and further screened against the eligibility criteria by groups of two authors (LG and LN; LG and IP). Any disagreements regarding inclusion were resolved by consensus and if consensus could not be reached, disagreements were resolved by a third author (MD).

Data extraction

Data were extracted from eligible studies by groups of two authors (LG and LN; LG and MP). These data included: (i) general study characteristics (e.g. title, author, year and country of publication and type of study); (ii) general study information (e.g. individual who delivered the intervention [e.g. clinician, student], professional qualification of individual delivering the intervention [e.g. chiropractor, physiotherapist], years of clinician experience/number of student hours, number of clinicians/students who delivered SM or SMob, recipient [e.g. human, manikin], number of recipients, whether the intervention was SM or SMob [and grade of mobilization], the region treated [e.g. cervical, thoracic] and the measurement equipment used to record force-time characteristics of the intervention); and (iii) force-time characteristics of SM (e.g. preload and peak forces, rate of force application). Data reporting on SMob will be published elsewhere (manuscript in preparation). Given the focus on describing and detailing studies that fulfilled eligibility criteria to enable the study aim to be fulfilled, no assessment of study quality was performed.

Data synthesis

Data are reported using descriptive statistics (mean, standard deviation and range) where possible. Deviations to this are indicated in the tables (e.g. 95% confidence intervals or median and interquartile range) and reflect how the data were reported in the original studies. Frequencies and proportions of trials reporting on each of the specified domains above were calculated in Microsoft Excel (Office 365, Microsoft Corporation, USA).

To streamline the large amount of data reported here, the following decisions were made regarding how to best report the data and are indicated in the tables: (i) for studies reporting forces measured in 3-dimensions (3D) and including the resultant forces (i.e. the total forces applied), only the resultant forces are reported; and (ii) for studies measuring forces applied in 3D but not including the resultant forces, only the forces measured in the primary direction of applied force are reported in the tables (e.g. for prone posterior-anterior thoracic SM, the vertical forces are reported). Regarding the reporting of metrological data of the equipment used to measure the

force-time characteristics, a consensus was reached by two authors (LG and MD) as to whether adequate information was provided. In cases where metrological details were reported (e.g. it was stated that calibration of equipment was performed and/or values for equipment accuracy were provided) but no further information was given and/or it was not possible to know how these values were obtained, this was recorded as metrological data were not provided. Considering definitions used in the literature to describe the duration of applied SM, considerable variability was observed. For example, the reporting of time to peak thrust force (i.e. from the end of preload to the peak force of the thrust) was often described as thrust duration [23], yet in other instances, both time to peak thrust force and thrust duration (i.e. the duration of force

application (e.g. [24]) were reported. To ensure the correct reporting of this data, the following steps were taken to determine which domain was reported: (i) when the definition was provided in the manuscript, this was used; (ii) if the definition was not provided but figure/s and/or graph/s were provided, these were used; and (iii) if the definition and figure/s and/or graphs were not provided, the terminology used by the original authors was kept. This decision was achieved by consensus of the two independent data extractors (LG and LN; LG and MP).

Results

There were 7,607 records initially identified by the electronic searches (Fig. 1). A total of 3,981 unique records remained after de-duplication (n=3,626). After title and

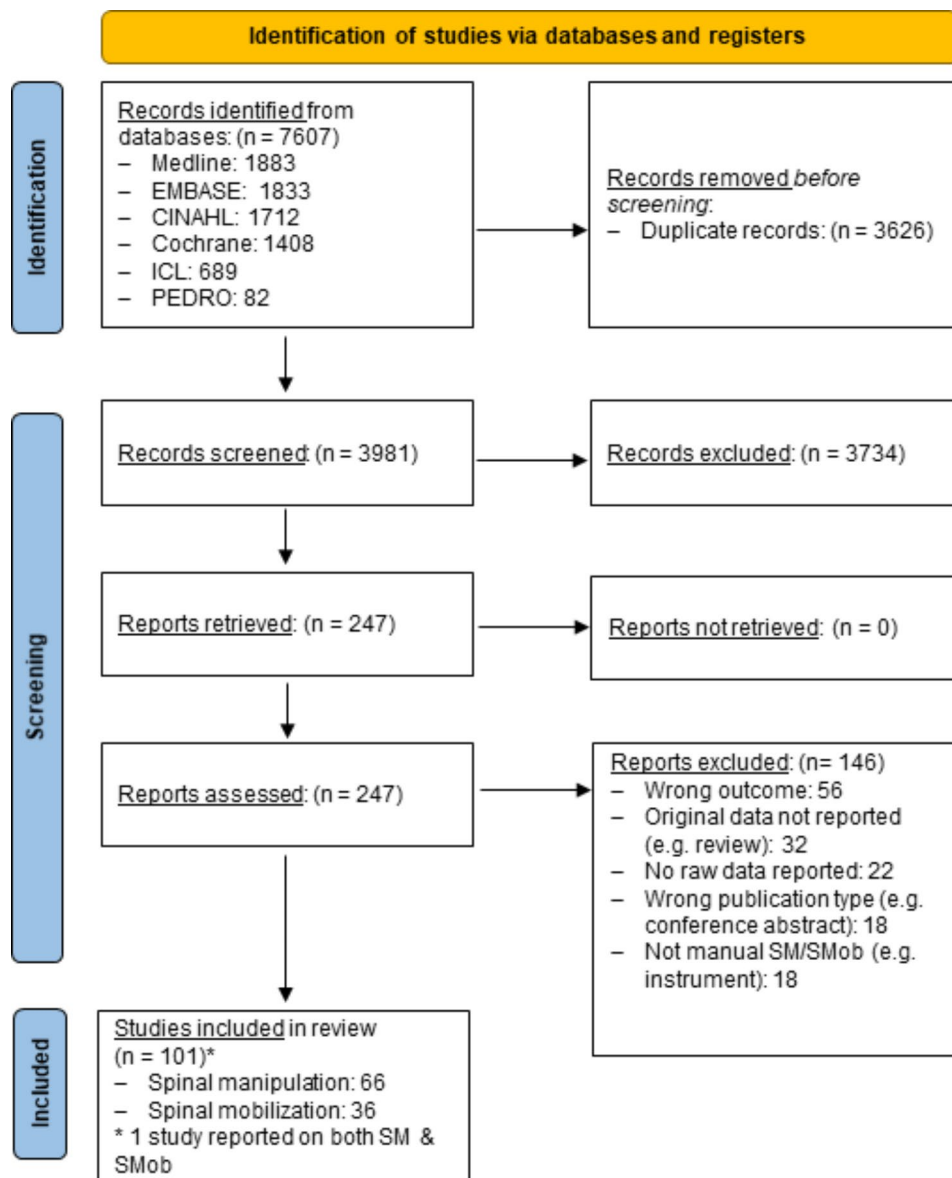

Fig. 1 PRISMA flow diagram

abstract screening, full texts of the 247 remaining reports were screened. Of these, 66 reported on SM, fulfilled the eligibility criteria and were included in the analysis. The reference list for these studies is provided in Appendix 2 and the reference number provided in each of the tables

relates to the numbering in this Appendix. The most common reasons for exclusion were: the paper reported on the wrong outcome (e.g. did not report on the force time parameters of SM (n=56)) and original data were not reported (e.g. the paper was a review (n=32)).

Table 1 Overall summary of studies reporting on the force-time characteristics of spinal manipulation (SM) (n = 66)

	n (%)		n (%)
Year, n = 66		Who received SM, n = 66	
2013 to 2022	30 (45.5)	Adult (18 to 65y)	27 (40.9)
2003 to 2012	18 (27.3)	Geriatric (> 65y)	1 (1.5)

Note: in instances where only one value is reported, data were only reported by one study. Abbreviations: Both: clinician-patient/equipment & patient/equipment-table, equip: equipment, man: manikin, ms: milliseconds, n: number of studies, N: Newtons, NR: not reported, s: seconds, tool: something to which SM was delivered (e.g. load cell), *: 15,592 N/s reported, likely a mistake [29], §: this is reported as N/ms, likely a mistake [30]

Of the 66 included studies, 30 (45.5%) were published in the previous 10 years (Table 1). Most studies were conducted in Canada (n=28, 42.4%), followed by the USA (n=23, 34.8%). Typically, the study design was cross-sectional (n=54, 81.8%), with SM delivered by clinicians only (i.e. no students were involved) (n=43, 65.2%), whose profession was chiropractic (n=57, 86.4%). In the 54 (81.8%) studies in which SM was delivered by clinicians, clinicians with more than 5 years of experience were most commonly involved (n=26, 47.3%). However, clinician experience was not reported in 18 (32.7%) studies. When SM was delivered by a student (n=23, 34.8%), the number of HVLA manual SM training hours was not reported in 20 (87.0%) studies. In most studies, the number of individuals (i.e. clinicians and/

or students) delivering SM was between 1-49 (n=50, 75.8%), with only 1-2 individuals delivering SM in 27 (54.0%) studies. SM was delivered to adults (18-65 years) in 27 (40.9%) studies, with the characteristics of the participants to which SM was delivered not reported in 11 (16.7%) studies. The number of individuals receiving SM was reported as between 1-49 in 59 (89.4%) studies, with only 1-2 individuals receiving SM in 28 (47.5%) studies. SM was most commonly delivered to the thoracic spine (n=40, 60.6%) and the lumbopelvic spine (n=19, 28.8%). The SM 'technique' (e.g. 'toggle', 'Diversified', 'Gonstead') was reported in 63 (95.5%) studies. Force-time characteristics were measured at the clinician-patient interface in 23 (34.8%) studies, the patient-table interface in 21 (31.8%) studies, both interfaces in 6 (9.1%) studies and

was not reported in 16 (24.2%) studies. Metrological data of the measurement equipment were not reported in 53 (80.3%) studies. Regarding force-time characteristics, the following were reported: preload force in 42 (63.6%) studies; peak force in 57 (86.4%) studies; rate of force application in 34 (51.5%) studies; time from end of preload force to peak force of thrust in 36 (54.5%) studies; and thrust duration in 21 (31.8%) studies.

Cervical spine

Of the 66 included studies, 12 (18.2%) reported on SM delivered to the cervical spine (Table 2). Of these 12 studies, SM was delivered to humans in 9 (75.0%) studies and to inanimate objects (i.e. human analogue manikins: 2 (66.7%); load cell: 1 (33.3%)) in 3 (25.0%) studies. Ranges of reported force-time characteristics are reported in Table 3 (summary) and Appendix 3, Table A (full).

Thoracic spine

Of the 66 included studies, 40 (60.6%) reported on SM delivered to the thoracic spine (Tables 4 and 5). Of these 40 studies, SM was delivered to humans in 27 (67.5%) studies and to inanimate objects (i.e. human analogue manikins: 12 (92.3%); strain gauge: 1 (7.7%)) in 13 (32.5%) studies. Ranges of reported force-time characteristics are reported in Table 3 (summary) and Appendix 3, Tables B-C (full).

Lumbopelvic spine

Of the 66 included studies, 19 (28.8%) reported on SM delivered to the lumbopelvic spine (Table 6). Of these 19 studies, SM was delivered to humans in 12 (63.2%) studies and to inanimate objects (i.e. human analogue manikins: 5 (71.4%); force transducer: 1 (14.3%); both a rigid table-top and a human analogue manikin: 1 (14.3%)) in 7 (36.8%) studies. Ranges of reported force-time characteristics are reported in Table 3 (summary) and Appendix 3, Table D (full).

No region specified

Of the 66 included studies, 6 (9.1%) reported on SM delivered to a non-defined region (Table 7). Of these 6 studies, SM was delivered to a tool in 3 (50.0%) studies, a force table/plate in 2 (33.3%) studies and a rigid surface in 1 (16.7%) study. Ranges of reported force-time characteristics are reported in Table 3 (summary) and Appendix 3, Table E (full).

Discussion

This review synthesised the current evidence describing force-time characteristics measured during the delivery of manual SM and highlights the considerable variability in these reported parameters. This finding is supported by an earlier systematic review by Downie and colleagues,

the only review to date reporting on the force-time characteristics of SM delivered to all regions of the spine [11] and a recent critical literature review by Gyer and colleagues who investigated dose-response effects of the force-time characteristics of SM [12]. The current work is not directly comparable to these previous reviews due to methodological differences (i.e. systematic vs. critical vs. scoping review) and reporting differences (i.e. preload and peak force only vs. preload and peak force, rate of force application, time from end of preload to peak thrust force and thrust duration and data reported for different spinal regions). Additionally, the current search captured 35 additional studies reporting on force-time characteristics measured during SM since the publication of the 2010 systematic review and included considerably more studies reporting on the thoracic (n=6 vs. n=27) and lumbar (n=7 vs. n=12) spines than the 2022 critical review. This highlights that the current review has exhaustively included studies reporting on force-time characteristics of SM and that there has been a large increase in the number of publications reporting on SM force-time characteristic data in the past ~13 years.

Despite this increased reporting, the heterogeneity of the existing literature precluded synthesis of the reported data beyond descriptive analysis. Such heterogeneity included the following factors: (i) there were many SM 'techniques' used within and between spinal regions; (ii) SM was delivered by individuals with a wide range of clinical experience (e.g. novice student to experienced clinician); (iii) biomechanical data were collected at different locations (e.g. clinician-patient and patient-table interfaces); and (iv) using a variety of equipment (e.g. pressure sensor, load cells, force plates). Conceivably, this heterogeneity is one reason for the large variability in reported force-time characteristics of SM. While these differences in SM delivery likely reflect the rich tapestry of clinical practice in which treatment is tailored to individual patients chosen by the clinician delivering the intervention, such differences prevent between-study comparisons of results and subsequent statistical synthesis. This is one reason that informed the decision to conduct a scoping, rather than a systematic review. A scoping review allowed this heterogeneity to be captured and thus, this study reports exhaustively the range of force-time characteristics quantifying the delivery of SM. As such, this study provides a comprehensive summary of the force-time characteristics of SM delivered to both humans and inanimate objects.

There is a push within the literature for authors to quantify and report both passive (i.e. SM) [25] and active interventions (e.g. exercise) [26] in sufficient detail to allow for their replication in future research studies. The quantification and subsequent detailed reporting of interventions would facilitate: (i) accurate replication

of the intervention in subsequent studies; (ii) improved interpretation of reported outcomes; and (iii) informed reader assessment regarding the applicability of both the intervention and reported outcomes to clinical practice [27]. However, it became evident during data extraction that detailed descriptions of several important items were not provided. Such items included vague or no reporting of: (i) the SM delivered; (ii) the individual who delivered the SM, especially their clinical training and experience; (iii) definitions of how each reported force-time characteristic was defined and/or calculated; (iv) information regarding the location of the applied SM; (v) the number of SM delivered; (vi) the number of SM recipients; and (vii) metrological details of the equipment used to quantify the force-time characteristics of SM.

Recommendations for reporting of SM

For specific examples and suggested descriptions for the recommendations made below, readers are referred to the template for intervention description and replication (TIDieR) checklist (cited above) published by Hoffmann and colleagues in 2014 which provides a guide to be used by: (i) authors, to more easily structure the reporting of their interventions; (ii) reviewers and editors, to assess the descriptions; and (iii) readers, to determine the relevance of the reported results [27]. For examples of detailed reporting specific to SM (as discussed below), readers are referred to the previously cited consensus paper discussing guidelines for the reporting of spinal manipulative therapy interventions [25] and to a recent publication discussing the reporting of measurement equipment metrological details in reference to the quantification of force-time characteristics during SM and SMob [28]. To address the reporting

deficiencies identified by the current review, the following general recommendations should be incorporated in future studies and their related publications. Firstly, there should be an adequate description of the applied SM technique. Regarding SM delivery, there should be sufficient detail so that an individual with manual therapy knowledge (e.g. manual therapy researchers, clinicians) would understand what was done and be able to replicate the intervention, including the primary direction of applied force (e.g. posterior-anterior), spinal region treated (e.g. thoracic) and level of treated segment (e.g. T3). Additional information regarding the location of the applied intervention (e.g. spinous process) should also be reported. The individual who delivered the SM should be described, including their training (e.g. physiotherapist, chiropractor) and experience delivering SM (e.g. students with X hours of experience delivering SM). Furthermore, the number of individuals delivering and receiving SM should be clearly reported, as should the number of SM that were delivered (i.e. how many thrusts were actually delivered). Secondly, definitions of how each reported force-time characteristic was defined and/or calculated need to be clearly reported. This allows for the comparison of data across multiple studies and will possibly facilitate meta-analysis of biomechanical data associated with dosage effects of SM in future clinical studies. Thirdly, as there is considerable variability in the reported force-time characteristics of SM, it is suggested that authors include raw data (i.e. non-analysed/non-averaged) to support their results where possible and that ranges are reported alongside other descriptive statistics (e.g. mean and standard deviation) for all reported force-time characteristics, allowing for a more illustrative description of the delivered SM. Finally, detailed description of the location of measurement (e.g. clinician-participant or participant-table) and measurement equipment used to quantify the force-time characteristics, including metrological details such as measurement error, reliability/repeatability, variability and calibration should be provided. With the use of appendices/supplementary files, it is feasible that these data are adequately reported while fulfilling editorial requirements (e.g. word limits).

Limitations

Limitations of the current study include that only manuscripts published in English, French or German were included in the search strategy. Furthermore, as this was a scoping (and not systematic) review, it is possible that some manuscripts reporting on the force-time characteristics of SM were inadvertently not captured by the search strategy. However, every attempt was made to avoid this situation, with a broad search strategy inclusive of many professions that routinely use SM to treat patients with musculoskeletal disorders conducted across

several databases, piloting and refinement of the search strategy prior to implementation, and the conduct of the scoping review in a systematic fashion (i.e. using two independent reviewers and data extractors). As such, it is unlikely that any seminal study was missed. Additionally, this review reports only on the kinetic force-time characteristics of SM and does not report on the kinematics of either the individual delivering the thrust and/or those of the recipient. Future reviews could address this gap in the literature by reporting on the kinematic parameters of individuals delivering SM (e.g. change in clinician centre of mass). Additionally, due to a lack of clarity regarding reported definitions of time to peak thrust force and thrust duration, it is possible that our best attempts to correctly classify this data were not sufficient. However, as two authors independently extracted the data prior to discussing and with a third author available for consensus resolution, it is unlikely that this lack of clarity in the original studies is a significant source of error within this study. Furthermore, it is not possible to determine the robustness/reliability of data collected using measurement equipment for which metrological data were not reported. Considering that this limitation applies to over three-quarters of the data reported here, the results should be interpreted with caution.

Conclusion

Considerable variability in the reported kinetic force-time characteristics of SM exists. Some of this variability is likely due to differences in SM delivery and the measurement equipment used to quantify force-time characteristics. However, improved reporting in certain key areas could facilitate more sophisticated syntheses of force-time characteristics data in the future. Such syntheses could provide the foundation upon which dose-response estimates regarding the clinical effectiveness of SM are made.
