6 Abstract

1

2

⁷ A Monte Carlo code has been developed to simulate resonant scattering ⁸ reactions using the thick gas target technique in inverse kinematics. Results ⁹ are presented for the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ reaction at 70 MeV, and compared to ¹⁰ an experimental measurement which utilised an array of segmented silicon strip ¹¹ detectors. In the case studied, angular straggling in the chamber window is ¹² found to dominate the excitation energy resolution.

16 1. Introduction

The technique of thick target resonant scattering provides an extremely use-17 ful tool in the study of α -cluster states [1], and has been used in a number 18 of experiments in recent years (see, for example, [2-12]). In this method the 19 scattering chamber is de-coupled from the beam line using a thin window (typ-20 ically Mylar[®] or Havar[®]), and filled with He gas. The He gas acts as both 21 the reaction target and an absorber to slow (and stop) the incoming beam. In 22 this way several resonances may be studied simultaneously with a single beam 23 energy, as the energy loss of the beam in the gas will result in a reduction in 24 the excitation energy with distance into the chamber. This is in contrast to a 25 more traditional thin target experimental setup, where many beam energies are 26 required to produce an excitation function. 27

Figure 1: (Colour online) Schematic chamber setup of a thick gas target resonant scattering experiment.

If the gas thickness and/or pressure is sufficiently high, and the beam heavier 28 than ⁴He (so that the beam stops in the gas before the scattered ⁴He recoils), 29 detectors may be placed on the beam axis (at 0°) inside the gas volume to de-30 tect the recoiling α -particles, without being damaged by the beam. This allows 31 reactions to be studied at 180° (in the centre-of-mass (CM) frame), an angle 32 where the non-resonant cross-section is typically much lower than the resonant 33 cross-section, allowing α -cluster states to be easily distinguished [1]. Detec-34 tors placed away from 0° allow α -particle angular distributions to be studied, 35 providing spin information for the resonances. 36

A schematic diagram of a typical chamber setup used in a thick gas target 37 resonant scattering experiment is shown in Fig. 1 (the detectors labelled DSSD 38 and LAMP are described in Section 3). The incoming beam will pass through 39 the thin window separating the vacuum tube and the He filled chamber, and 40 begin to lose energy in the gas. At some distance into the chamber the beam will 41 interact with a He nucleus and form a resonance in the compound system. This 42 resonance will subsequently decay, most likely back into the beam species and 43 an α -particle. For example, in the case of the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ reaction studied 44 in this work, the ${}^{4}\text{He}$ and ${}^{20}\text{Ne}$ form a resonance in the compound nucleus ${}^{24}\text{Mg}$, 45

ACCEPTED MANUSC

before decaying back into a 20 Ne nucleus and an α -particle. Usually it is only the 46 recoiling α -particle that is detected, as the heavier scattered beam experiences 47 greater energy loss and tends to stop before reaching the detectors. In the 48 case of the ${}^{4}\text{He}({}^{6}\text{He},\alpha){}^{6}\text{He}$ reaction studied in [2], however, it was possible to 49 detect both the ⁶He and α -particle in coincidence, due to the relatively low mass 50 and charge of the ⁶He. A coincidence measurement is typically cleaner than a 51 singles experiment, as the need for explicit particle identification is removed 52 (particle identification being easily obtained from the particle energy and two-53 body kinematics). In the case of the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ reaction studied here, 54 particle identification was also not an issue, as the detectors were placed (see 55 below) at such a distance that the ²⁰Ne was always stopped in the gas. Hence 56 the assumption that any hit was an α -particle was generally good (the cross-57 section for decay of the resonant ²⁴Mg to an exit channel other than α + ²⁰Ne 58 being small). 59

In some reactions it is possible that particles other than recoiling α -particles 60 may be detected. For example, in the ${}^{4}\text{He} + {}^{14}\text{O}$ study of [3], a large background 61 of protons was seen (the ${}^{4}\text{He}({}^{14}\text{O,p}){}^{17}\text{F}$ reaction has a positive Q-value of + 1.1962 MeV). In this experiment time of flight techniques were used to give particle 63 identification, making use of the pulsed nature of the cyclotron beam employed 64 in the measurement. This allowed lower energy α -particles to be detected than 65 would have been the case if a ΔE -E telescope had been employed (as was the 66 case in, for example, [11]). The particle identification techniques of time of 67 flight, ΔE -E energy loss and pulse shape discrimination, may also be required in 68 experiments utilising a window with a large hydrogen content (such as Mylar[®]) 69 or Kevlar[®]), the use of which will most likely produce a significant flux of 70 protons liberated from the window material. Scattering of the beam from the 71 window (as opposed to the He gas) to detectors placed away from 0° can be 72 removed by using a collimator placed inside the gas volume. Such a collimator 73 was used to reduce background from scattered beam in the LAMP array used 74 in the ${}^{4}\text{He} + {}^{6}\text{He}$ measurement of [2], for example. 75

76

The thick target resonant scattering technique uses inverse kinematics, and

is therefore especially useful in studying reactions that would otherwise require 77 a radioactive target (such as, for example, 10 Be in the case of [11] or 14 C in the 78 case of [12]), a gas target (such as in the ${}^{4}\text{He} + {}^{36}\text{Ar}$ reaction studied in [8]), or 79 both (the ${}^{4}\text{He} + {}^{6}\text{He}$ [2] and ${}^{4}\text{He} + {}^{14}\text{O}$ [3] reactions, for example, can in fact 80 only be measured using inverse kinematics, due to the 800 ms half-life of ⁶He and 81 70.6 s half-life of 14 O). However, determining the experimental resolution and 82 detection efficiency of such measurements can be challenging, due to the large 83 variation in position of the interaction point within the chamber, and hence the 84 need to track the beam and outgoing particles through the gas. The use of 85 detector arrays with complicated geometry (such as that illustrated in Fig. 1) 86 is an additional problem. 87

One technique that is ideally suited to modelling thick target resonant scat-88 tering experiments is that of Monte Carlo simulation. Simulations can be per-89 formed using either general purpose codes, such as GEANT4 [13], or custom 90 codes used for specific fields of research, such as cluster breakup [14], nuclear 91 astrophysics [15] and Coulomb dissociation [16]. Monte Carlo codes have been 92 used to model a wide range of detection systems, ranging from β -decay detectors 93 (for example [17, 18]), neutron arrays (for example [19, 20]) and semiconductor 94 Ge detectors (for example [21, 22]). This paper reports on a new Monte Carlo 95 simulation that has been written to aid both the planning of thick gas target 96 resonant scattering experiments, and to help in the interpretation of the data 97 obtained. 98

99 2. Monte Carlo simulation code REX

The Monte Carlo code REX (Resonant EXcitation simulation) is written in Fortran, and generates pseudo-events in a form that may be analysed using the same analysis codes as used for real experimental data. This allows a direct comparison between any simulated and experimental spectra of interest, aiding the analysis of real data and the interpretation of results.

105

At the start of each simulated event REX randomly chooses an excitation

energy (E_r) for the scattering interaction from within a user defined distribution 106 (either a uniform distribution or a series of one or more Gaussian line shapes 107 of user defined energy, Full Width at Half Maximum (FWHM) and relative 108 strength). After making an allowance for the beam energy spread, beam diver-109 gence, beam spot size, beam steering (offset away from the centre of the beam 110 line) and window, three main processes are simulated as the beam is tracked 111 through the chamber. The first is energy loss (ΔE), which is calculated using a 112 subroutine version of the code DEDX [23]. The second effect is energy straggling 113 (E_{strag}) , which is simulated by adding a randomly chosen energy to that of the 114 beam. This random energy is chosen from within a Gaussian distribution (cen-115 tred at zero) of width given by the formalism of Clarke [24]. The third process 116 is angular straggling (θ_{strag}) . This is similar to energy straggling, in that ran-117 domly chosen angles are added to both the in-plane (θ_x) and out-of-plane (θ_y) 118 angles of the beam. These random angles are chosen from a Gaussian distribu-119 tion (again centred at zero) of width determined from the multiple scattering 120 equations of Marion and Zimmerman [25]. The effects of energy and angular 121 straggling are therefore to smear the energy and angles of the beam by random 122 (and energy dependent) amounts. 123

After determining the effects of energy loss, energy straggling and angular 124 straggling in the window, the beam is tracked through the gas in user defined 125 steps. At the end of each step ΔE , E_{strag} and θ_{strag} are calculated for that 126 step, allowing the energy, Cartesian (X, Y, Z) coordinates of the beam particle 127 (the origin being defined as the centre of the window) and the distance to the 128 window to be calculated. The absolute particle in-plane (θ_x) and out-of-plane 129 (θ_{y}) angles are also determined, as are those relative to the centre of the window. 130 From these the polar (θ) and azimuthal (ϕ) angles can also be determined. The 131 absolute polar angle (θ_{abs}) and that relative to the window (θ_{win}) are illustrated 132 in Fig. 1. Hence at the end of each step the energy, position within the chamber 133 and direction of travel of the beam particle are known. 134

The tracking of the beam continues until the energy loss is such that the initially chosen E_x has been reached. At this point the scattering is simulated,

with the CM scattering angle being chosen from either a uniform, Rutherford or Legendre Polynomial distribution. The energies of the outgoing particles are determined from two-body kinematics, and then they are tracked in the same manner as the beam - at the end of each step the effects of ΔE , E_{strag} and θ_{strag} are calculated, and the particle energies, positions and angles (both absolute and with respect to the window) obtained.

Both outgoing particles are tracked until one of four possible outcomes is 143 met: 1) the energy reaches zero and the particle stops in the gas, 2) the particle 144 hits an active region of a detector, 3) the particle hits the non-active frame of 145 a detector (this simulating the shadowing of detectors further from the window 146 by those closer) and 4) the particle reaches a (user defined) maximum distance 147 from the window without stopping or hitting a detector. In event types 1, 3 148 and 4 the particle does not hit an active region of a detector and is lost. Once 149 a particle has been determined to have hit a detector (event type 2, described 150 below) a check is made to ensure the energy is greater than the detector energy 151 threshold, and then the energy and position of the particle smeared by the 152 detector energy and position resolution. Events in which either one or both of 153 the particles hit a detector are then written to the output file in the form of 154 pseudo-events, ready for analysis. 155

Three categories of detector may be simulated by REX. Detectors placed on 156 the beam axis (at 0°) may be either round (such as surface barrier detectors) or 157 rectangular (such as resistive strip or double sided strip detectors). Rectangular 158 detectors may also be placed at any point in the chamber (centred at (R, θ, ϕ)) 159 (in spherical polar coordinates) with respect to the window), with a tilt angle 160 between 0° (perpendicular to the beam axis) and 90° (parallel to the beam axis). 161 The third category of detectors are Micron Semiconductor Ltd [27] type YY1 162 detectors [28], used to form the "LAMP" array (as shown in Fig. 1 and described 163 in Section 3.1). The dimensions of the active regions of the detectors as well 164 as any surrounding frames are used to determine if a particle has hit or missed 165 the detectors. Any number of missing or broken strips may also be simulated. 166 Detector hits are determined by comparing the angles and distance from the 167

window of the particles at the end of each gas step, with the angular coverage 168 and distances of each detector. If the particle angles lie within the range covered 169 by a detector strip, a check is made on the relative distance from the window 170 of the particle and the detector at that (angular) point. If the particle distance 17 (R_p) is less than the detector distance (R_d) , the particle has not yet reached 172 the detector, and another gas step simulated. If $R_p = R_d$ (within a tolerance 173 equal to a tenth of the gas step size) the particle is said to have hit the detector. 174 If $R_p > R_d$ the particle has "passed through" the detector. In this case the 175 last gas step is undone and a new gas step (equal to half of the previous step) 176 simulated. In this way any particle hitting the detector within the active region 177 will register a hit. A similar method is used to determine if the particles hit the 178 frame surrounding the detector active region. 179

In addition to ΔE , E_{strag} and θ_{strag} in the window and gas, REX can 180 also simulate the same effects arising from absorber foils placed in the beam 181 (before and/or after the window). The effects of beam energy spread from the 182 accelerator, beam divergence and beam spot size, may be simulated by adding 183 a random energy, angle or distance (from a Gaussian distribution centred at 184 zero) to the beam energy, in-plane and out-of-plane angles and in-plane and 185 out-of-plane distances from the window, at the start of each event, respectively. 186 Any offset in the beam from the centre of the window can also be simulated. 187 The effect of a collimator placed inside the chamber (after the window) may 188 be simulated, as can the energy loss, energy straggling and angular straggling 189 through a series of 0° silicon detectors forming a $\Delta E - E$ telescope (as used in, 190 for example, [11]). The detector position resolution can take the form of either 191 a Gaussian distribution (for resistive strip detectors) or the strip centroid (for 192 non-resistive strip detectors such as those used in the LAMP array in [2, 11]). It 193 is possible to turn each smearing effect on or off (in any combination), allowing 194 the contribution of each to the excitation energy resolution (for example) to be 195 196 studied.

¹⁹⁷ 3. Results and discussion

¹⁹⁸ 3.1. The ${}^{4}He({}^{20}Ne,\alpha){}^{20}Ne$ reaction

The ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ reaction has been simulated in order to compare the 199 output of REX to experimental data. The experiment [26] was performed at 200 the GANIL accelerator facility in Caen, France. A 70 MeV 20 Ne beam was used 201 in conjunction with a chamber filled to 540 torr with He gas. The window was 202 4.8 μ m Havar[®]. The detector setup consisted of one double sided silicon strip 203 detector (DSSD) (Micron Semiconductor Ltd [27] type W1) and one LAMP 204 [2, 11]) array (as shown in Fig. 1). The DSSD was (5×5) cm² in active area, 205 with 16 horizontal 3 mm wide strips on one face and 16 vertical 3 mm strips 206 on the other. This was placed at 0° (on the beam axis) and 360 mm from the 207 window. The LAMP array was constructed from 6 Micron Semiconductor Ltd 208 type YY1 detectors [28], a schematic of which is shown in Fig. 2. Each YY1 209

Figure 3: (Colour online) Schematic of the LAMP array used in the experiment of [26]. The side view shown at the bottom corresponds to a line through $\phi = 90^{\circ} - 270^{\circ}$ (in the front view, above).

USCIP

detector consists of a 45° wide wedge shaped PCB (with inner and outer radii of 210 40 and 145 mm, respectively) and an active silicon region consisting of 16 non-211 resistive 5 mm wide radial strips. The inner strip (labelled 1 in the following 212 discussions) has an inner radius of 50 mm, and the outer strip (labelled 16) an 213 inner radius of 125 mm. The inner 13 strips cover an absolute azimuthal width of 214 $\phi \approx 40^{\circ}$, which reduces to $\approx 36^{\circ}$, 29° and 19° for the outer 3 strips [28]). When 215 8 YY1 detectors are placed together they form a flat and completely circular 216 (360°) annular array, LEDA [28]. With the removal of two detectors a 6 sided 217 cone shaped configuration (known as LAMP) can be created, as shown in Figs. 1 218 and 3. In the front view of LAMP, shown at the top of Fig. 3, the azimuthal 219

Parameter	Value	Parameter	Value
Beam energy	$70 { m MeV}$	Beam energy spread	200 keV
He gas pressure	540 torr	Beam divergence in X	0.5°
Window material	$\operatorname{Havar}^{\mathbb{B}}$	Beam divergence in Y	0.5°
Window thickness	$4.8~\mu{\rm m}$	Beam spot size in X	$6.6 \mathrm{mm}$
LAMP distance	$284~\mathrm{mm}$	Beam spot size in Y	$1.6 \mathrm{mm}$
DSSD distance	$360 \mathrm{~mm}$	Detector energy resolution	$100 \ \mathrm{keV}$
Gas step size	$1 \mathrm{mm}$	Detector energy threshold	$1.2 { m MeV}$

Table 1: Values for the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ simulations.

angles of the 6 detector centres can be seen to be 30°, 90°, 150°, 210°, 270° 220 and 330°. In this view the detectors appear foreshortened, as they are tilted 221 towards the beam line (out of the page) by triangular shaped mounting blocks. 222 These can be seen in the side view, taken along the line $\phi = 90^{\circ}$ to 270°, which 223 is shown at the bottom of Fig. 3. The mounting blocks hold the YY1 detectors 224 at an angle of 46° (the angle between the detector face and beam axis), and 225 three pairs of such blocks, with a 60° separation, give the 6 sided cone shaped 226 arrangement seen at the top of Fig. 3, and in the chamber schematic shown in 227 Fig. 1. Each of the 6 mounting blocks are attached to a frame, which is used to 228 hold the LAMP array at the correct height with respect to the beam axis. In the 229 ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ experiment [26] simulated, the distance along the beam axis 230 from the window to the inner edge of strip 1 (the strip closest to the beam axis) 231 was 284 mm. At this distance the active region of each YY1 detector mounted 232 in the LAMP array covered an azimuthal angle (as seen from the window) of \approx 233 56° . 234

Additional details of the experimental setup (used as inputs to REX) are given in Tab. 1. The majority of the simulations were performed with a gas step of 1 mm (and hence a detector hit tolerance of 0.1 mm). The effect of varying the gas step and hit tolerance is discussed below.

239 3.2. Resonance Distance

The results of an investigation into the position within the chamber of a 240 series of resonances are presented in Fig. 4. Here the distance from the window 241 is shown for 7 resonances, generated (with equal weighting) in 1 MeV steps, 242 between $E_x = 11$ and 17 MeV. In the main panel the resonance distance is 243 plotted separately for events detected in the DSSD and the 16 strips of the 244 LAMP array. In the upper panel all events are shown projected together onto 245 the distance axis. The distance of the resonances varies from 34.3 mm from the 246 window for the resonance at $E_x = 17$ MeV, to 270.4 mm for that at $E_x = 11$ 247 MeV. Also indicated in Fig. 4 are the distances from the window of the 0° DSSD 248 (360 mm) and the LAMP array. The outer edge of the outer strip (strip 16) 249 of the LAMP array lies at a distance of 228.4 mm from the window (along the 250 beam axis), and the inner edge of the inner strip (strip 1) at 284.0 mm. It can 251 be seen, therefore, that the resonances at $E_x = 11$ and 12 MeV sit within the 252 cone of the LAMP array. This results in an excitation energy threshold for the 253 LAMP strips. For example, events in which scattering is simulated at $E_x = 11$ 254 MeV cannot be detected in any of the 16 strips of the LAMP detectors. This is 255 because the α -particle produced in the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ reaction cannot scatter 256 to large enough angles (due to two-body kinematics) to hit the detectors with 257 sufficient energy to overcome the energy thresholds. In addition, only strips 1 258 and 2 can detect events from the 12 MeV resonance, and strips 1-9 that at E_x 259 = 13 MeV. All 16 strips can detect events generated at $E_x = 14$ MeV and above. 260 In contrast, and due to its positioning within the chamber, all 7 resonances can 261 be detected in all strips of the 0° DSSD. Such investigations will provide useful 262 information when planning the setup of future experiments. 263

The resonances shown in Fig. 4 were generated with an excitation energy width of 1 keV. Due to energy straggling of the beam in the window and gas, this translates to a FWHM of approximately 4 mm in position within the chamber. It is necessary, therefore, to use a gas step that is smaller than 4 mm in the simulations, to ensure correct sampling of the resonances. As mentioned previously, the majority of results were obtained with a step size of 1 mm, although

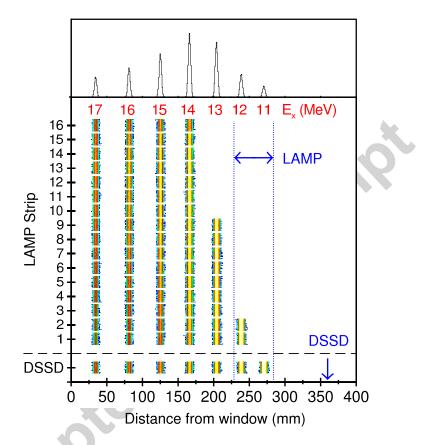

Figure 4: (Colour online) Distance from the window (along the beam axis) for a series of 1 keV wide resonances, generated at $E_x = 11 - 17$ MeV, as detected in the DSSD and LAMP detectors of [26]. The distance to the 0° DSSD (360 mm) and coverage of the LAMP array (228.4 to 284.0 mm) are indicated. The upper panel shows the projection of all events onto the distance axis.

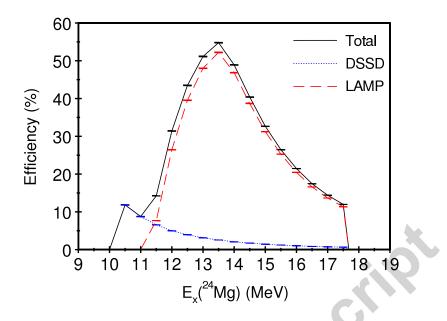

Figure 5: (Colour online) Efficiency profile for the 0° DSSD (blue dotted line), LAMP array (red dashed line) and overall value (black solid line) in the experiment of [26].

steps of 0.1, 0.2, 0.5, 1.5 and 2.0 mm have also been investigated (see below).

271 3.3. Geometrical Detection Efficiency

The geometrical detection efficiency obtained from REX for the experimental 272 setup of [26] is shown in Fig. 5. The maximum excitation energy reached in the 273 experiment is determined by the energy of the beam directly after the window, 274 $E_x = 17.68$ MeV. The minimum excitation is given by the reaction Q-value, 9.31 275 MeV. However, as events occurring at excitation energies close to the reaction Q-276 value will produce outgoing particles with very low kinetic energies, in practice 277 this minimum excitation energy is not seen, due to the energy thresholds set 278 on the detector signals to remove noise. Hence the actual detected E_x range is 279 10.08 – 17.68 MeV. In Fig. 5 the efficiencies are plotted in 0.5 MeV E_x steps 280 for both the 0° DSSD detector (blue dotted line) and LAMP array (red dashed 281 line). Also shown is the total efficiency (black solid line). The excitation energy 282 threshold of the LAMP array discussed in Section 3.2 may be seen in Fig. 5, 283

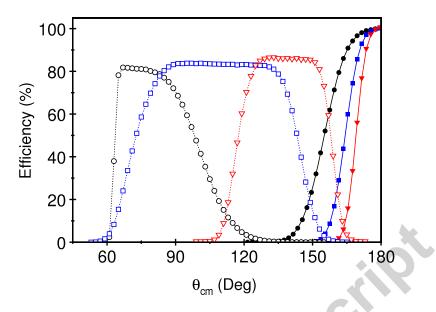

Figure 6: (Colour online) Efficiency profile for the 0° DSSD (solid lines and closed points) and LAMP array (dotted lines and open points) of [26] against CM scattering angle, for excitation energies of 12 (black lines and circles), 14 (blue lines and squares) and 16 (red lines and triangles) MeV.

the LAMP efficiency being zero at 11 MeV. This is in contrast to the 0° DSSD
efficiency, which is 8.75 % at this point.

The efficiencies of the 0° DSSD and LAMP array of [26] are shown as a 286 function of CM scattering angle in Fig. 6, for excitation energies of 12, 14 and 287 16 MeV. The excitation energy threshold of the LAMP array (seen in Fig. 5) 288 also appears in Fig. 6 as a sharp cut-off in the 12 MeV (black dotted line 289 with open circles) distribution at $\theta_{cm} \sim 60^{\circ}$. Despite this, it can clearly be 290 seen that the various distributions become narrower and centred towards larger 291 CM angles, as the excitation energy increases. This is because high E_x values 292 correspond to smaller distances into the chamber (as seen in Fig. 4) and hence 293 greater distances from the detectors. This in turn leads to a reduction in the 294 solid angles covered by the detectors with respect to the resonance point, and 295 hence a narrowing of the efficiency profiles. The shift to smaller (more forward) 296 laboratory angles arising from this translates as a shift to higher CM angles, 297

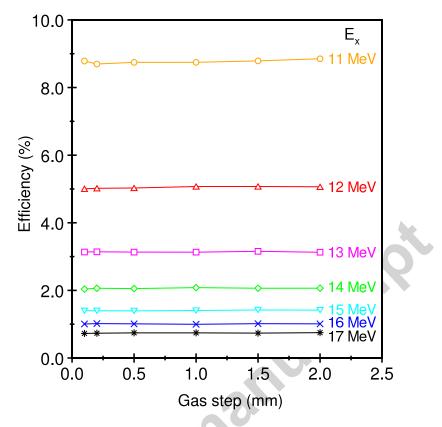

Figure 7: (Colour online) Efficiency for the 0° DSSD of [26] as a function of REX gas step size, for excitation energies of 11 (orange line with circles), 12 (red line with deltas), 13 (magenta line with squares), 14 (green line with diamonds), 15 (cyan line with triangles), 16 (blue line with crosses) and 17 (black line with stars) MeV.

²⁹⁸ due to the use of inverse kinematics in the reaction. As the 0° DSSD is situated ²⁹⁹ on the beam axis in the scattering chamber, the three DSSD profiles shown in ³⁰⁰ Fig. 6 all reach 100 % efficiency at $\theta_{cm} = 180^{\circ}$. This is in contrast to the LAMP ³⁰¹ array, which has a maximum efficiency of only 81 – 86 %, a result of the gaps ³⁰² in the azimuthal coverage that arise from the PCB surrounding the silicon on ³⁰³ the YY1 detectors.

In Fig. 7 the efficiency of the 0° DSSD is shown as a function of the gas step size used in the REX simulations (0.1, 0.2, 0.5, 1.0, 1.5 and 2.0 mm). Resonances have been simulated at 1 MeV intervals between 11 and 17 MeV. In

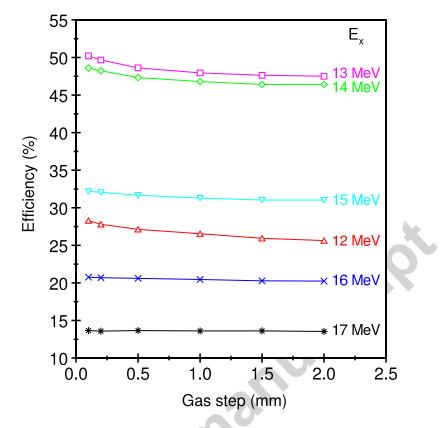

Figure 8: (Colour online) Efficiency for the LAMP array of [26] as a function of REX gas step size, for excitation energies of 12 (red line with deltas), 13 (magenta line with squares), 14 (green line with diamonds), 15 (cyan line with triangles), 16 (blue line with crosses) and 17 (black line with stars) MeV.

- all cases the data are independent of the gas step size used, within the statistical fluctuations of the simulations. The uncertainties vary from absolute efficiency values ± 0.05 % at $E_x = 11$ MeV, to ± 0.008 % at $E_x = 17$ MeV (and as such are too small to be shown in Fig. 7).
- The effect of altering the gas step size on the LAMP efficiency is shown in Fig. 8, and a clear dependence may be observed. The greatest effect is seen at E_x = 12 MeV, where the efficiency obtained with a step of 2.0 mm, (25.63 ± 0.07) %, increases to (28.29 ± 0.08) % for a step of 0.1 mm, an absolute difference of ~ 2.7 %. The variation decreases with increasing excitation energy, however,

so that by $E_x = 17$ MeV the difference in efficiencies for the 2.0 and 0.1 mm 316 steps, (13.54 ± 0.04) % and (13.65 ± 0.04) % respectively, is only ~ 0.1 %. The 317 dependence observed in Fig. 8 results from the sensitivity of the efficiency to 318 the solid angle of the detector strips, which in turn depends on the accuracy 319 to which the position of the resonance can be determined within the chamber. 320 The effect is greatest at $E_x = 12$ MeV, as this resonance sits within the cone 321 of the LAMP array (as seen in Fig. 4). The effect decreases with increasing 322 excitation energy, as the higher excitation resonances are increasingly further 323 from the LAMP array. While such an effect should also be seen for the 0° 324 DSSD, it is further from the resonances than the LAMP array, and mounted 325 perpendicularly to the beam axis. This reduces the variation in efficiency with 326 gas step (as seen in the tilted detectors of LAMP), to the extent that the effect 327 is not seen in Fig. 7. As the data obtained with LAMP are only used to study 328 angular distributions, and the yield is not required to be efficiency corrected 329 to produce an excitation energy spectrum (in barns), the variation in efficiency 330 with gas step size does not pose a real issue in the analysis of experimental data. 331 The results shown in Figs. 7 and 8 were obtained by varying the gas step size. 332 This in turn resulted in a variation in the detector hit tolerance (as described 333 in Section 2), as this is set to 10 % of the gas step. Simulations have also been 334 performed with a fixed tolerance of 0.1 mm at all gas steps. The results are the 339 same as those shown in Figs. 7 and 8, and are not presented. These simulations 336 show that the variation in efficiency with gas step size seen in Fig. 8 for the 337 LAMP array is not due to the changing hit tolerance condition. 338

339 3.4. Resolution

The excitation energy of resonances populated in thick gas target resonant scattering reactions may be obtained from the detected energy, E_d , of the α particle. This requires a simulation of the reaction in which only energy loss effects are considered. A polynomial fit to the distribution of detected energies as a function of the simulated excitation energy, generated with a uniform distribution, allows E_x to be determined from E_d on an event by event ba-

sis. To remove any angular effects, a polynomial is obtained for each detector 346 strip, or, in the case of a DSSD, for each of the "pixels" formed by the crossing 347 of one front and one back strip. Once these polynomials have been obtained, 348 the E_x resolution of the experimental setup may be studied by running further 349 simulations, in which narrow (FWHM = 1 keV) resonances are generated. By 350 observing the width with which these resonances are reconstructed in the data 351 analysis, the E_x resolution may be determined. As each smearing effect can be 352 turned on or off in any combination in REX, the contribution from each to the 353 total E_x resolution may be obtained. 354

Fig. 9 shows the excitation energy obtained from the detected α -particle 355 energy, for a REX simulation of a resonance at 16 MeV, for all of the pixels of 356 the 0° DSSD of [26] added together. In Fig. 9(a) the results of a simulation 357 with all smearing effects turned off (except energy loss in the window and gas) 358 are shown. The smooth red line shows the results of a Gaussian peak fit to 359 the Monte Carlo data (stepped black line), indicating a FWHM of 11 keV. The 360 width is not the 1 keV width of the resonance as generated, because although 361 all smearing effects were turned off in the simulation, the effect of the detector 362 position resolution is always included in all simulations. This arises from the use 363 of a polynomial fit, to obtain the excitation energy from the detected energy, for 364 each detector pixel (or strip in the case of the LAMP array). No matter where 365 the hit is within the pixel (or strip), the same polynomial will always be used 366 to obtain E_x . This mimics the position resolution of the detector, as no matter 367 the position within a pixel (or strip), only the pixel (or strip) centroid angle is 368 known for that hit. 360

The effect of turning on the angular straggling of the beam in the window is shown in Fig. 9(b), and simulating all effects together in Fig. 9(c). In Fig. 9(b) the FWHM has increased from the 11 keV seen in Fig. 9(a), to 52 keV. The width of the resonance seen in Fig. 9(c) is 63 keV. This indicates that a significant contribution to the overall E_x resolution arises from the angular straggling of the beam in the window. This is supported by the results obtained at 11 – 15 and 17 MeV, as given in Tab. 2. Also listed in Tab. 2 are the

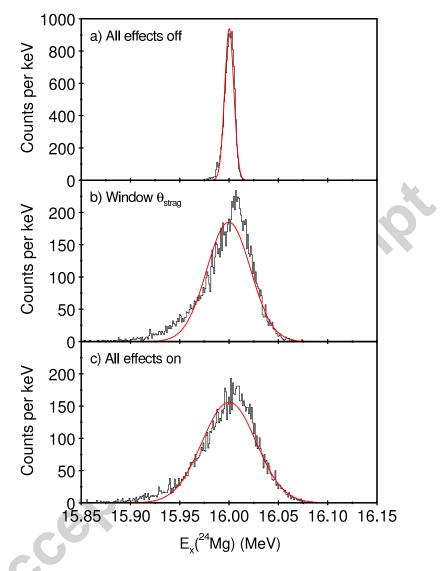

Figure 9: (Colour online) Reconstructed E_x spectra for the 0° DSSD of [26] obtained from REX for a state generated at $E_x = 16$ MeV with a) all smearing effects off, b) angular straggling of the beam in the window simulated and c) all smearing effects simulated. In all panels the smooth (red) line is the result of a Gaussian peak fit to the data (stepped black line). The results are for all DSSD pixels added together.

contributions for each of the other smearing effects, obtained by running the 377 simulations multiple times, with each effect turned on individually in turn. At 378 all excitations it can be seen that the angular straggling of the beam in the 379 window dominates the overall resolution. The effect of angular straggling in 380 the window is to deviate the beam, so that it is no longer travelling along the 381 beam axis. The equations of Marion and Zimmerman [25] allow the FWHM of 382 the angular straggling distribution to be predicted. For a 70 MeV 20 Ne beam 383 passing through a 4.8 μ m Havar[®] foil, the FWHM is 1.74°. A beam particle 384 scattering at an angle equal to the Half Width at Half Maximum (0.87°) would 385 arrive at the 17 MeV resonance (34.3 mm from the window, Fig. 4) 0.5 mm from 386 the beam axis, whereas at the 11 MeV resonance (270.4 mm from the window) 387 the deviation would be 4.1 mm, over a full DSSD strip width away. This gives 388 rise to the increasing resolution contribution with decreasing excitation energy, 389 as seen in Tab. 2. In contrast, the widths listed for the angular straggling of 390 the α -particle in the gas are the same as those obtained with all effects turned 391 off, indicating that this effect is negligible. 392

The 0° DSSD E_x resolution, obtained with all effects off, angular straggling 393 of the beam in the window, and all effects turned on, is plotted as a function of 394 excitation energy in Fig. 10. As noted above, the contribution of the angular 395 straggling of the beam in the window (blue delta points and dotted line) may 396 be seen to be dominant at all excitation energies. It is clear, therefore, that one 397 way to improve the experimental excitation energy resolution would be to reduce 398 the window thickness, and hence the effect of angular straggling on the beam. 399 As a reduction in window thickness would result in a decrease in mechanical 400 strength, a reduction in the gas pressure may also be required. This is turn may 401 lead to a need to increase the detector distance, to ensure coverage of the same 402 E_x range. Such changes are discussed below. 403

⁴⁰⁴ In Fig 11 the excitation energy obtained from the detected α -particle energy ⁴⁰⁵ is shown for strip 16 (the outer strip) of the LAMP array of [26]. As in the ⁴⁰⁶ 0° DSSD case (Fig. 9), these results were obtained from a simulation of a ⁴⁰⁷ resonance at $E_x = 16$ MeV. In Fig. 11(a) the result obtained with all smearing

Table 2: Predicted E_x resolution contributions (FWHM in keV) for the 0° DSSD of [26]. The term beam divergence represents the effect of the initial beam angular dispersion, and the term beam spot of the initial beam position dispersion. Energy and angular straggling are labelled E_{strag} and θ_{strag} , respectively. Fitting uncertainties are < 1 keV in all cases. The results shown are for all DSSD pixels together.

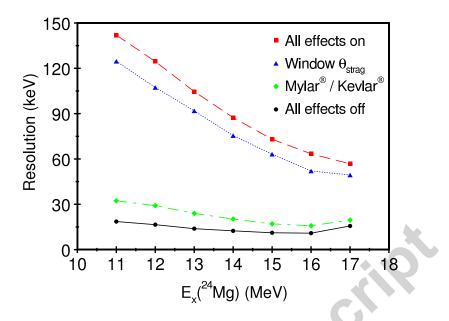

Figure 10: (Colour online) REX predicted E_x resolution (FWHM) for simulations with all smearing effects off (black circular points and solid line), angular straggling of the beam in the window (blue delta points and dotted line) and all smearing effects on (red square points and dashed line) for the 0° DSSD of [26], as a function of excitation energy. The green diamond points and dot-dashed line indicate the resolution contribution for a Mylar[®] or Kevlar[®] window (see Section 3.5). The results are for all DSSD pixels added together.

effects turned off is shown. The distribution is non-Gaussian, and has a width 408 (indicated by the vertical dotted red lines) of 102 keV, with a fitting error of \pm 409 8 keV. As described above, simulations with all effects turned off do include the 410 detector position resolution. The width of the distribution seen in Fig. 11(a) for 411 the LAMP array is much greater than that seen in Fig. 9(a) for the 0° DSSD. 412 This is because the LAMP strips are significantly bigger than the (3×3) mm 413 pixels of the 0° DSSD (the outer strip of a Micron Semiconductor Ltd type YY1 414 detector [28] is 5 mm high and approximately 42 mm wide). This results in a 415 much greater range of distances and scattering angles (and hence excitation 416 energies) that can be detected in a single strip of LAMP, when compared to 417 a pixel of the 0° DSSD. In Fig. 11(b) the results with the angular straggling 418 of the beam in the window only turned on are shown. The width obtained 419

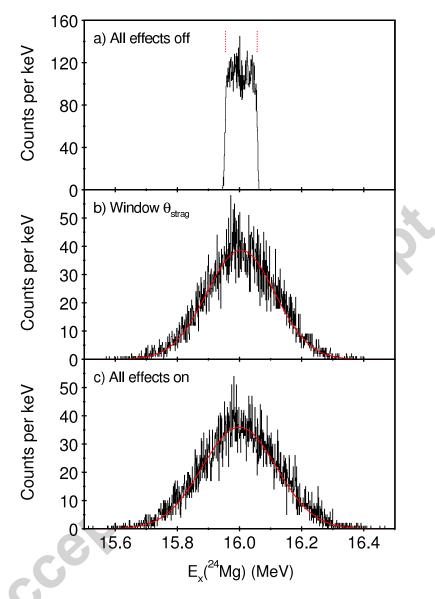

Figure 11: (Colour online) Reconstructed E_x spectra for the outer strip ($\theta_{\text{win}} = 22.0^\circ$) of the LAMP array of [26] obtained from REX for a state generated at $E_x = 16$ MeV with a) all smearing effects off, b) angular straggling of the beam in the window simulated and c) all smearing effects simulated. In a) the vertical dotted (red) lines indicate the width of the distribution. In b) and c) the smooth (red) line is the result of a Gaussian peak fit to the data.

from a Gaussian peak fit (indicated by the smooth red line) is 259 keV. As was the case for the 0° DSSD, the angular straggling of the beam in the window dominates the overall E_x resolution for the LAMP array, which has a FWHM of 281 keV (Fig. 11(c)) for strip 16 at $E_x = 16$ MeV. All other strips exhibit similar behaviour, and the spectra are not presented.

In Tabs. 3, 4, 5 and 6 the contributions from all smearing effects are listed 425 for LAMP strips 1 ($\theta_{\text{win}} = 7.9^{\circ}$), 6 ($\theta_{\text{win}} = 12.1^{\circ}$), 11 ($\theta_{\text{win}} = 16.8^{\circ}$) and 16 (θ_{win}) 426 $= 22.0^{\circ}$), respectively. Most contributions are small, and close to those with 427 all effects turned off. As such these smearing effects display a non-Gaussian 428 E_x distribution (labelled "N"), due to the domination of the detector position 429 resolution. In contrast, effects labelled "G" have a Gaussian peak shape in 430 the reconstructed excitation energy spectrum (such as seen in Figs. 11(b) and 431 11(c)). These include the effect of angular straggling of the beam in the window, 432 which in all cases dominates the overall resolution, and the overall resolution 433 itself. 434

The LAMP resolutions as a function of excitation energy, obtained from 435 simulations with all effects off, angular straggling of the beam in the window, 436 and all effects turned on, are shown in Fig. 12, for (a) strip 1, (b) strip 6, (c) strip 437 11 and (d) strip 16. As seen in Fig. 10 for the 0° DSSD, the angular straggling 438 of the beam in the window (blue dotted line) dominates the overall resolution 439 (red dashed line) at all excitation energies. Reducing the window thickness is 440 therefore again seen as a way to improve the experimental excitation energy 441 resolution (see below). 442

The effect of varying the gas step size on the 0° DSSD excitation energy 443 resolution is shown in Fig. 13. Resonances were generated in 1 MeV steps 444 between 11 and 17 MeV, and gas steps of 0.1, 0.2, 0.5, 1.0, 1.5 and 2.0 mm were 445 used. The fitting errors on the resolution values shown are < 1 keV in all cases. 446 It can be seen in Fig. 13 that at all excitations the resolutions drop between 2.0 447 and 1.0 mm, but then converge to a constant value (to within $\approx 2 \text{ keV}$) between 448 1.0 and 0.1 mm. This suggests that step sizes above 1.0 mm are too coarse 449 to correctly sample the 4 mm FWHM of the resonances (seen in Fig. 4). The 450

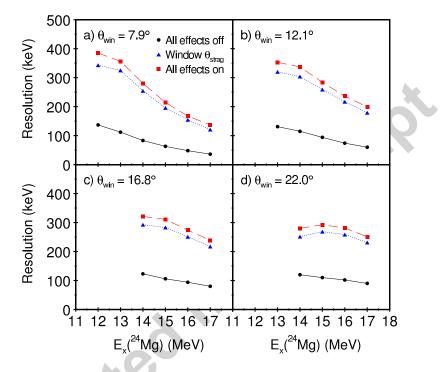

Figure 12: (Colour online) REX predicted E_x resolution (FWHM) for simulations with all smearing effects off (black circular points and solid line), angular straggling of the beam in the window (blue delta points and dotted line) and all smearing effects on (red square points and dashed line) for a) strip 1 ($\theta_{win} = 7.9^\circ$), b) strip 6 ($\theta_{win} = 12.1^\circ$), c) strip 11 ($\theta_{win} =$ 16.8°) and d) strip 16 ($\theta_{win} = 22.0^\circ$) of the LAMP array of [26].

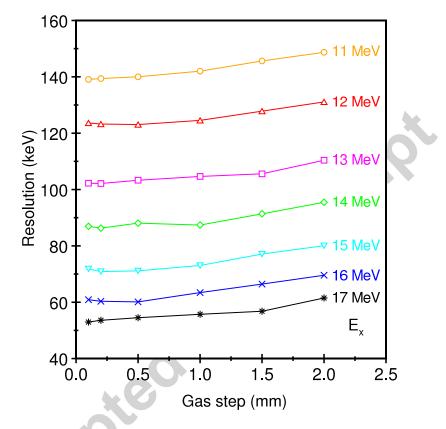

Figure 13: (Colour online) Resolution (FWHM) for the 0° DSSD of [26] as a function of REX gas step size, for excitation energies of 11 (orange line with circles), 12 (red line with deltas), 13 (magenta line with squares), 14 (green line with diamonds), 15 (cyan line with triangles), 16 (blue line with crosses) and 17 (black line with stars) MeV. The results are for all DSSD pixels added together.

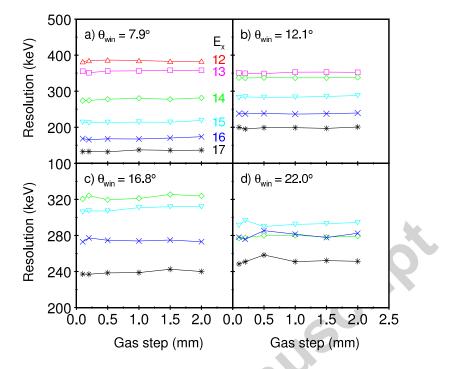

Figure 14: (Colour online) Resolution (FWHM) as a function of REX gas step size, for excitation energies of 12 (red line with deltas), 13 (magenta line with squares), 14 (green line with diamonds), 15 (cyan line with triangles), 16 (blue line with crosses) and 17 (black line with stars) MeV for a) strip 1 ($\theta_{win} = 7.9^{\circ}$), b) strip 6 ($\theta_{win} = 12.1^{\circ}$), c) strip 11 ($\theta_{win} = 16.8^{\circ}$) and d) strip 16 ($\theta_{win} = 22.0^{\circ}$) of the LAMP array of [26].

maximum resolution variation observed between 1.0 and 0.1 mm occurs at E_x 451 = 16 MeV. Here the average resolution is 61.8 keV and the variation 3.3 keV, 452 or 5.3 %. The average variation (which gives an indication of the uncertainty of 453 the REX resolution predictions due to the step size choice) across all excitations 454 is 3.0 %. The results presented in Fig. 13 were obtained with a hit tolerance 455 of 10 % of the gas step size. As for the case of detection efficiency discussed 456 previously, repeating the simulations with a fixed hit tolerance of 0.1 mm did not 457 produce any variations in the resolutions obtained. These results are therefore 458 not presented. 459

In Fig. 14 the resolution of the LAMP array of [26] is shown as a function of the gas step size used in the simulations, for strips 1, 6, 11 and 16. The

error on each value from the peak fitting routine used to obtain the resolutions 462 is ≤ 2 keV, in all cases. The resolutions are essentially independent of gas step 463 size at all excitation energies, the maximum variation being seen for strip 16 at 464 $E_x = 17$ MeV (black line with stars in Fig. 14(d)). In this case the maximum 465 variation is 10 keV, with the average resolution across all step sizes being 252 466 keV. This corresponds to a maximum variation in REX predicted resolution 467 for the LAMP array of 4.0 %. Across all strips, gas step sizes and excitation 468 energies, the average variation is 2.3 %. The dependence on gas step size seen 469 in Fig. 13 for the 0° DSSD is not seen for the LAMP array in Fig. 14. This is 470 because the LAMP resolution is much worse than that for the 0° DSSD, such 471 that other effects (for example the strip position resolution) dominate. As was 472 the case for the 0° DSSD, simulations in which a fixed hit tolerance of 0.1 mm 473 was used did not alter the results shown in Fig. 14. 474

475 3.5. Excitation Energy

In Fig. 15(a) a $^{24}\mathrm{Mg}$ excitation energy spectrum, obtained from a study 476 of the ${}^{20}\text{Ne}(\alpha,\alpha_0){}^{20}\text{Ne}$ reaction in standard kinematics [29], is shown. The 477 spectrum exhibits a rich structure of states in the 12.5 - 18.5 MeV E_x range, 478 and consists of 664 data points, each corresponding to an individual beam energy 479 setting of the accelerator. This data has been used to investigate the accuracy 480 of the REX resolution predictions for the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ data of [26]. A 481 polynomial fit was made to the REX resolution values obtained with all smearing 482 effects turned on, as a function of excitation energy, for the 0° DSSD (red dashed 483 line in Fig. 10). The data shown in Fig. 15(a) were then convoluted with a 484 Gaussian line shape, with a varying width taken from the polynomial fit to the 485 REX resolution. This allows a prediction to be made of the excitation energy 486 spectrum that should be obtained from the 0° DSSD of [26] (the data of [29] 487 has a resolution of only a few keV, and is therefore a very accurate measure of 488 the true ²⁴Mg excitation energy spectrum). The result is shown by the black 489 solid line in Fig. 15(b). Also shown (red dotted line) is the experimental ^{24}Mg 490 excitation energy spectrum obtained from the 0° DSSD of [26]. The agreement 491

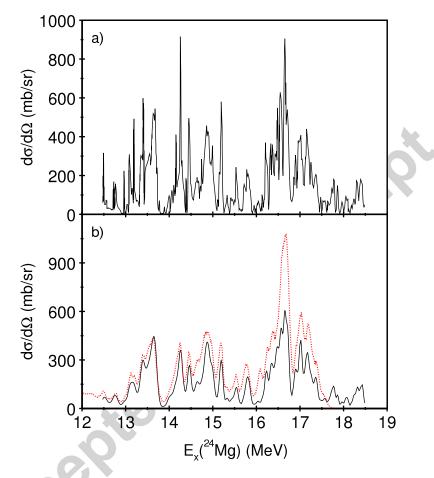

Figure 15: (Colour online) a) ²⁴Mg E_x spectrum from the ²⁰Ne $(\alpha,\alpha_0)^{20}$ Ne reaction [29] and b) ²⁴Mg E_x spectra obtained from the ²⁰Ne $(\alpha,\alpha_0)^{20}$ Ne reaction of [29] convoluted with the REX predicted resolution of [26] (black solid line) and from the ⁴He $(^{20}$ Ne $,\alpha)^{20}$ Ne reaction [26] (red dotted line).

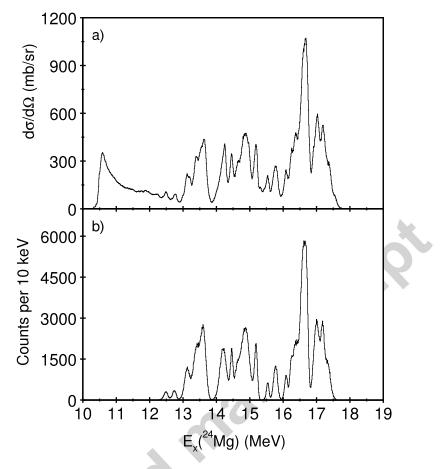

Figure 16: ²⁴Mg E_x spectra for the ⁴He(²⁰Ne, α)²⁰Ne reaction from the a) data of Walshe *et al.* [26] and b) REX simulation.

⁴⁹² in terms of the general structure and widths of the features is excellent (the ⁴⁹³ absolute magnitudes do vary, however, as the data of [29] was taken at a CM ⁴⁹⁴ angle of 168° and that of [26] at 180°). This comparison suggests that the ⁴⁹⁵ resolutions predicted by the REX simulations are reliable.

⁴⁹⁶ By generating a series of resonances with varying centroids, widths and rela-⁴⁹⁷ tive strengths, it is possible to reconstruct an excitation energy spectrum using ⁴⁹⁸ REX. This is illustrated in Fig. 16. In Fig. 16(a), the experimental ²⁴Mg E_x ⁴⁹⁹ spectrum obtained from the 0° DSSD of [26] is shown, and in Fig.16(b) a REX ⁵⁰⁰ generated reproduction. The REX spectrum was obtained by generating 20 res-

onances between 12.5 and 17.3 MeV, with widths varying from 47 to 262 keV. 501 The agreement between Figs. 16(a) and 16(b) is excellent, the only discrep-502 ancy being the Rutherford scattering background underlying the experimental 503 data, which has not been included in the REX simulation. On this occasion the 504 REX spectrum was produced after the experimental data had been analysed 505 (the centroids, widths and relative strengths of the resonances used to generate 506 Fig. 16(b) were obtained from a fit to Fig. 16(a)). However, REX can also be 507 used to predict the outcome of any future resonant scattering experiment, by 508 simulating the E_x spectrum that would be obtained (using the known centroids 509 and widths of states in the nucleus of interest, listed in compilations and data 510 tables, for example). By altering the experimental parameters used as inputs to 511 REX, such as the detector configuration and distance to the window, gas pres-512 sure, window thickness and window material (for example, $Mylar^{
entropy}$ or $Kevlar^{
entropy}$ 513 could be substituted for Havar[®], if the expected beam intensity is low), the 514 best setup (in terms of both efficiency and resolution) can be determined. 515

516 3.6. Window Material

The effect of varying the window material has been investigated by perform-517 ing simulations using Mylar[®] and Kevlar[®]. The window thickness used in the 518 experiment of [26], 4.8 μ m, was used in both cases, but the beam energy altered 519 to compensate for the differing energy loss through the different foils. For the 520 Havar[®] window used in [26], the energy loss is such that the 70 MeV beam exits 521 the foil (and enters the gas) at 50.22 MeV. Beam energies of 56.11 and 56.32 522 MeV were used for the Mylar[®] and Kevlar[®] simulations, respectively, to give 523 this same energy. The E_x resolution contribution, arising from angular strag-524 gling of the beam in the window, is shown in Fig.10, for the 0° DSSD of [26]. As 525 described in Section 3.4, the blue delta points and dotted line shows the angular 526 straggling contribution from the Havar[®] window, which can be seen to domi-527 nate the overall resolution (red squares and dashed line) of the experiment. The 528 angular straggling contributions obtained from the Mylar[®] and Kevlar[®] win-529 dow simulations are identical to within 0.5 keV at all excitations, and hence an 530

averaged value for both materials is shown in Fig.10 (green diamond points and 531 dot-dashed line). It can be seen that the angular straggling contribution from 532 Mylar[®] and Keylar[®] windows is significantly lower than that from Havar[®]. 533 indicating that Mylar[®] and Keylar[®] provide the best choice of window mate-534 rial (if the beam current is low enough to allow their use). This is supported 535 by the results for the LAMP array of [26]. The angular straggling contribution 536 for the Havar[®] window of [26] is shown by the blue delta points and dotted 537 line in Fig.12 (described in Section 3.4), and again can be seen to dominate the 538 overall experimental resolution. The results for Mylar[®] and Kevlar[®] windows 539 have been found to be indistinguishable from those obtained with all smearing 540 effects turned off (black circular points and solid line in Fig.12), and are not 541 shown. This suggests that the contributions from angular straggling of the beam 542 in these window materials is much smaller than those arising from the LAMP 543 strip position resolution. 544

The difference in angular straggling contributions from Mylar[®], Kevlar[®] 545 and Havar[®] result from the different compositions of the materials. Mylar[®] 546 (composed of C, H and O) and Kevlar[®] (composed of C, H, O and N) have much 547 lower average masses, charges and densities than Havar[®] (composed mainly of 548 Co, Cr, Ni and Fe). Because Havar[®] consists almost entirely of metals, it 549 is both mechanically strong and an excellent conductor. This allows the heat 550 arising from the energy loss of the beam as it passes through the foil to be easily 551 dissipated. In contrast, Mylar[®] and Keylar[®] are both insulators, and will likely 552 melt under exposure to high beam currents. In a radioactive beam experiment, 553 where the beam currents are typically low, it may be possible to use Mylar[®] or 554 Kevlar[®] windows without risking a catastrophic failure due to melting (in the 555 experiment of [2] a 2.5 μ m Mylar[®] window was used with a beam intensity of 556 $\sim 2 \times 10^6$ particles per second, although the gas pressure was only 150 mb). 557 For higher beam intensities a Havar[®] window may well have to be used, or at 558 the very least Mylar[®] or Kevlar[®] with a thin aluminium coating. 559

To illustrate the advantages of using a thinner and lighter window, a simulation has been performed for the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ reaction of [26], in which

Mylar[®] was used instead of Havar[®]. The window thickness was reduced (by 562 a factor of two) to 2.4 μ m, and the gas pressure halved (to 270 torr) to reflect 563 the use of a thinner (and weaker) window. To account for the lower energy 564 loss through the Mylar[®], a beam energy of 53.20 MeV was used. This gives 565 the same 50.22 MeV into the gas as the setup of [26]. As the resonances will 566 be spread further into the chamber due to the use of a lower gas pressure, the 567 LAMP and 0° DSSD distances were increased to 535 and 740 mm, respectively. 568 These settings result in the same excitation energy range being covered by each 569 detector in the two configurations, as seen in Fig. 17. Here the efficiency profiles 570 are shown for both the experimental setup of [26] (previously shown in Fig. 5) 571 (black solid lines) and for the new simulation (blue dotted lines). In the case of 572 the 0° DSSD (Fig. 17(a)) the efficiency is seen to drop by a factor of 4.4, a result 573 of the approximately doubling of the window to DSSD distance (from 360 to 740 574 mm). As the distances of the resonances into the chamber have also doubled 575 (the $E_x = 17$ MeV resonance moves from 34.3 (Sec. 3.2) to 68.3 mm, and that 576 at $E_x = 11$ MeV from 270.4 to 540.5 mm) the resonance to DSSD distances have 577 also increased. For example, at $E_x = 17$ MeV, the resonance to DSSD distance 578 (R_r) is 360.0 - 34.3 = 325.7 mm at 540 torr and 740.0 - 68.3 mm = 671.7 579 mm at 270 torr, a ratio of 671.7/325.7 = 2.1. As the solid angle covered by the 580 DSSD with respect to the resonance point depends on $1/R_r^2$, a change in R_r by 581 a factor of 2.1 leads to a decrease in solid angle by a factor of $2.1^2 = 4.4$. Hence 582 the drop in efficiency seen for the 0° DSSD in Fig. 17(a) results entirely from 583 the changing geometry of the two experimental setups simulated. In the case of 584 the LAMP array (Fig. 17(b)) the efficiency profile appears narrower, and the 585 peak shifted towards lower excitation, in the new simulation. This again results 586 from the increased resonance to detector distance, which leads to a reduction 587 in the angular range covered by the array. For example, at 284 mm the centre 588 of the inner strip is at $\theta_{\rm win} = 7.9^{\circ}$, which reduces to 4.2° at 535 mm. For the 589 outer strip the angle changes from 22.0° at 284 mm to 10.9° at 535 mm. It it 590 this narrowing of the angular range of the LAMP array at 535 mm that leads 591 to the corresponding narrowing of the efficiency profile. Despite this, it can be 592

seen in Fig. 17 that the excitation energy range covered is the same for both
 experimental setups.

In Figs. 18 and 19 the excitation energy resolution is shown for the experi-595 mental setup of [26] (black solid line) (previously shown in Figs. 10 and 12) and 596 for the new simulation (blue dotted line). For both the 0° DSSD (Fig. 18) and 597 LAMP array (Fig. 19) the improvement in resolution is clear, and arises from 598 the reduction in angular straggling of the beam in the window in the proposed 599 improved setup. In the case of the 0° DSSD (Fig. 18) the resolution reduces 600 to approximately 30 keV at all excitations, a decrease by a factor of 4.1 at E_x 601 = 11 MeV and 2.0 at 17 MeV. For the 4 strips of the LAMP array shown in 602 Fig. 19, the resolution drops by a factor of a minimum of 2.3 (Strip 1 at E_r 603 = 12 MeV and Strip 16 at $E_x = 14$ MeV) and a maximum of 4.2 (Strip 11 at 604 $E_x = 17$ MeV). It is clear, therefore, that unless limited by low beam intensity 605 (and hence low counting statistics) it would, in general, be better to use the 606 thinnest Mylar[®] or Kevlar[®] window possible in future work. Although this 607 would require lowering the gas pressure and pushing the detectors further from 608 the window (when compared to a measurement using a thick Havar[®] foil), the 609 decrease in efficiency would be compensated by the much greater experimental 610 resolution, and hence quality of the data obtained. 611

612 3.7. Angular Distribution

In both the ${}^{4}\text{He}({}^{6}\text{He},\alpha){}^{6}\text{He}$ measurement of [2], and the ${}^{4}\text{He}({}^{10}\text{Be},\alpha){}^{10}\text{Be}$ 613 reaction studied in [11], spin information was obtained for the resonances ob-614 served following a study of the α -particle angular distributions. These may be 615 simulated in REX, an example for the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ reaction being shown 616 in Fig. 20. Here the detected α -particle energy has been plotted against angle 617 with respect to the window (which has been smeared randomly within the range 618 of the pixel or strip hit in the event). In Fig. 20(a) the angular distribution 619 is shown for the experimental data of [26]. The data observed between 0° and 620 5.8° correspond to that obtained from the 0° DSSD, and that between 7.5° and 621 22.5° to the LAMP array. A series of loci can be seen, each corresponding to 622

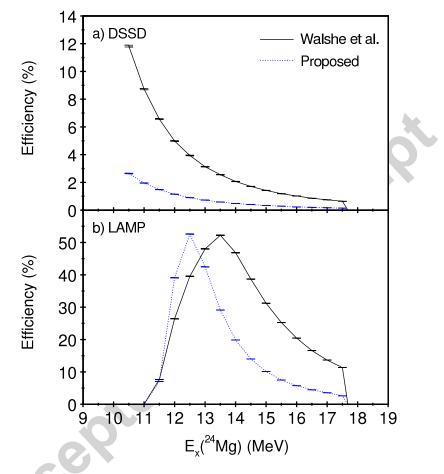

Figure 17: (Colour online) Efficiency profiles for the experiment of [26] (black solid lines) and proposed improved setup (see text) (blue dotted lines) for the a) 0° DSSD and b) LAMP array.

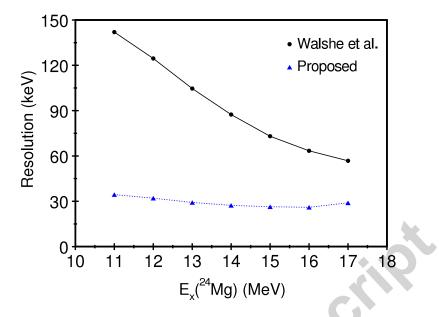

Figure 18: (Colour online) REX predicted E_x resolution (FWHM) for the 0° DSSD of [26] (black solid line) and proposed improved setup (see text) (blue dotted line).

one of the individual resonances seen in Fig. 16(a). In Fig. 20(b) a REX gener-623 ated version of the same angular distribution is shown. This was obtained from 624 the same simulation used to produce the excitation energy spectrum shown in 625 Fig.16(b). In general, the agreement in coverage between Figs. 20(a) and 20(b)626 is excellent, with the only discrepancy being in the low energy $(E_d < 10 \text{ MeV})$ 627 region. This arises because in the experimental data Rutherford scattering is 628 observed in the DSSD, and noise seen in the LAMP array. Neither of these 629 effects are included in the REX simulation. The REX spectrum shown in Fig. 630 20(b) was produced in a simulation in which a uniform angular distribution was 631 used for the scattering. This results in an intensity pattern that varies smoothly 632 with angle, and which reflects the detection efficiency of the experimental setup. 633 This is in contrast to the experimental data (Fig. 20(a)), in which much greater 634 variations in intensity can be observed in the loci as a function of angle, a result 635 of the spins of the resonances. This difference can be clearly seen in the regions 636 surrounding the solid black line in both panels of Fig. 20, which represents the 637

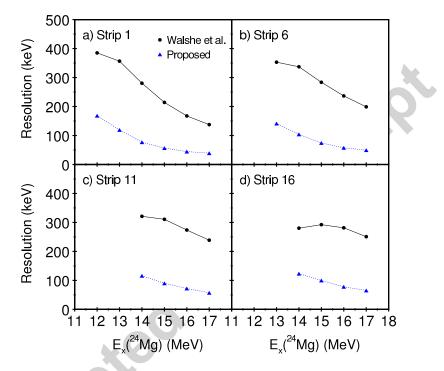

Figure 19: (Colour online) REX predicted E_x resolution (FWHM) for strips a) 1, b) 6, c) 11 and d) 16 of the LAMP array of [26] (black solid line) and proposed improved setup (see text) (blue dotted line).

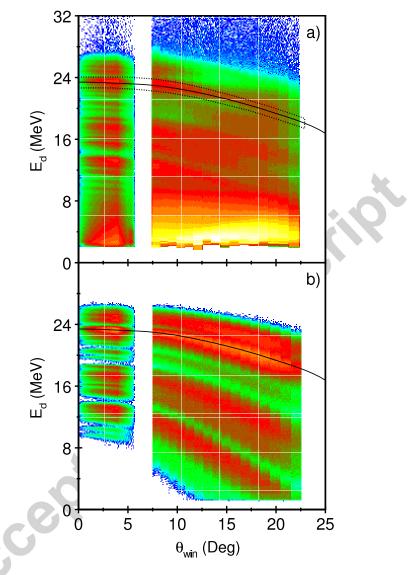

Figure 20: (Colour online) Detected energy against angle for a) the data of [26] and b) a REX simulation. In both panels the solid black line shows a REX simulation of a resonance at E_x = 16.64 MeV, with all smearing effects off. The dotted line in a) indicates the window used to select events (see text).

result of a simulation for a single resonance at $E_x = 16.64$ MeV, obtained from REX with all smearing effects turned off. The intensity in the region of this line in Fig. 20(b) varies smoothly with angle, whilst in Fig. 20(a) the experimental data can be seen exhibit much more variation.

In Fig. 21 the projection of the experimental angular distribution seen within 642 the dotted window in Fig. 20(a) is shown. Also shown are the results of REX 643 simulations for a single $E_x = 16.64$ MeV resonance, obtained with differing 644 Legendre polynomial (P_L) angular distributions for the scattering reaction. In 645 Fig. 21(a) the results of a simulation with L = 3 are shown, in Fig. 21(b) the 646 results for L = 4 and in Fig. 21(c) L = 5. No single L value can reproduce 647 the data, although a simple sum of 72 % L = 3 and 28 % L = 5 (without 648 any interference included) does provide a reasonable description, as seen in 649 Fig. 21(d). Performing additional simulations for all of the resonances seen in 650 Fig. 20(a) would allow the spins to be investigated and the dominant L values 651 determined. 652

653 4. Summary

A Monte Carlo code (REX) has been developed in order to simulate thick 654 gas target resonant scattering experiments. After simulating the effects of the 655 beam energy spread from the accelerator, beam divergence, beam spot size, 656 beam offset from the centre of the window and the window itself, the beam is 657 tracked in steps through the gas. After each step the effects of energy loss, energy 658 straggling and angular straggling on the beam energy, position and trajectory 659 are determined. Once the interaction point has been reached, the scattering 660 reaction is simulated, and the outgoing particles then tracked in steps in a 661 similar manner to the beam. For events in which a particle hits a detector, the 662 effects of detector energy and position resolution are simulated, and the event 663 written to a file for analysis. 664

Simulations of the ${}^{4}\text{He}({}^{20}\text{Ne},\alpha){}^{20}\text{Ne}$ reaction have been performed, the efficiency and resolution investigated, and the excitation energy spectrum and

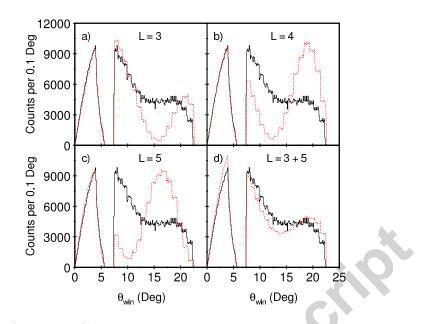

Figure 21: (Colour online) Angular distribution for the resonance at $E_x = 16.64$ MeV in the data of [26] (black solid line) overlaid with the REX prediction (red dotted line) for a) L = 3, b) L = 4 and c) L = 5. In d) the weighted sum of L = 3 (72 %) and 5 (28 %) is shown.

angular distribution reproduced. Comparisons to the experimental results of a measurement performed at GANIL [26] indicate the results obtained from REX are reliable. The excitation energy resolution is found to be dominated by angular straggling in the window, indicating that the window thickness and material (and hence gas pressure and detector distances) must be considered carefully in the planning of future experiments.
