26 Abstract

27 *Objectives*: To investigate rates of clinically significant externalizing behavior in young adult

survivors of pediatric TBI, and evaluate the contribution of pre- and post-injury risk and

29 resilience factors to externalizing behaviour outcomes 16 years after injury.

30 *Setting:* Melbourne, Australia

31 *Participants*: Fifty-five young adults (*M* age = 23.85; Injury Age: 1.0 - 12 years) admitted to

an emergency department following TBI between 1993 and 1997.

33 *Design*: Longitudinal prospective study with data collected at the acute, 10-year and 16-year
 34 post-injury time points.

35 *Main Measures*: Severity of TBI, adaptive functioning, family functioning, full scale IQ,

36 executive functioning, social communication, and symptoms of externalizing behavior (EB).

37 *Results*: One of every four young people with a history of pediatric TBI demonstrated clinical

38 or sub-threshold levels of EB in young adulthood. More frequent externalizing behavior was

associated with poorer pre-injury adaptive functioning, reduced full scale IQ and more

40 frequent pragmatic communication difficulty.

41 Conclusion: Pediatric TBI is associated with elevated risk for externalizing disorders in the

42 transition to adulthood. Results underscore the need for screening and assessment of TBI

43 among young offenders, and suggest that early and long-term targeted interventions may be

44 required to address risk factors for EB in children and young people with TBI.

50

Introduction

A growing number of research studies, undertaken within various national contexts, consistently demonstrate a disproportionately high prevalence of traumatic brain injury (TBI) amongst youth and adult offending populations. Studies estimate that between 12% and 24% of the general population have experienced a head injury resulting in loss of consciousness¹⁻⁴. This compares to equivalent reported rates of between 32% and 46% amongst young people in custody ⁵⁻⁸, with several studies suggesting over 60% of adult prisoners have experienced a head injury with loss of consciousness ⁹⁻¹¹.

Studies of adult offending populations seldom indicate whether TBI was sustained in 58 childhood or adulthood. Nonetheless research has repeatedly demonstrated that 'life-course 59 60 persistent' offending typically begins in childhood and is commonly associated with 'neurocognitive impairments' ^{12,13}. This would suggest that children experiencing pediatric 61 TBI are at elevated risk for persistent offending beyond adolescence, and that their 62 experiences run counter to the norm of desistence from criminality during young adulthood 63 ^{14,15}. Despite this apparent association between TBI and persistent adult offending, to date 64 there is insufficient research regarding such behavior in the transition into young adulthood 65 amongst those who experience pediatric TBI. 66

There is considerable evidence that pediatric TBI contributes to impairments in 67 executive functions, cognitive skills and EB (such as aggression, hyperactivity, bullying and 68 defiance) that are commonly identified as risk factors for antisocial behavior and criminality. 69 TBI commonly involves pathology to anterior brain regions implicated in executive 70 functioning, as well as traumatic axonal injury that may contribute to deficits in social 71 cognition, attention, learning difficulties and pragmatic communication¹⁶⁻¹⁸. Impairments in 72 executive functioning have been detected soon after injury and appear to persist or even 73 worsen with time since injury ¹⁹⁻²¹, likely reflecting a failure to develop and acquire skills at 74

an age appropriate rate ²². It may be that such deficits contribute to antisocial or offending
behavior through decreased inhibition, poor anticipation of the consequences of specific
actions, or an inability to recognise when certain behavior is inappropriate in a given social
context ^{23,24}.

Reduced cognitive empathy implies an inability to see the consequences of antisocial 79 behavior or to empathize with victims²⁵. These deficits are a common consequence of 80 pediatric TBI, particularly among children with frontal injuries ²⁶. In addition, children and 81 adolescents with TBI experience persisting difficulty interpreting non-verbal emotion cues 82 83 from facial expressions and prosody, as well as impairments in social or pragmatic communication ^{22,27}. These deficits are likely to contribute to reduced interpersonal 84 85 effectiveness, which may in turn lead to frustration and distress, reflected in EBs that are shown to persist or even worsen with time since injury ²⁸⁻³¹. 86

Though persisting injury-related neurocognitive impairments may elevate risk for 87 antisocial or offending behavior after TBI, criminological research suggests that such injuries 88 may influence offending via exposure to social and environmental experiences that may 89 exacerbate the neurological consequences of brain injury³²⁻³⁴. For example, studies have 90 linked permissive or authoritarian parenting styles, poor parental mental health and lower 91 socio-economic status to long-term behavioral problems following TBI ³⁵⁻³⁸. Persistent 92 problems in academic performance, including specific difficulties in reading, spelling and 93 arithmetic are commonly reported after TBI ³⁹⁻⁴², and are likely to have a cumulative impact 94 95 on educational opportunities, leading to challenges in engaging in later stages of education, particularly in the transition to secondary school ⁴³⁻⁴⁶. 96

97 The Heuristic Model of Social Competence (HMSC) ⁴⁷ provides a useful framework
98 for conceptualizing how such a range of injury and non-injury related risk and resilience
99 factors may contribute to variability in social functioning after TBI, and can therefore be

100 usefully applied to the study of crime and antisocial behavior. Injury related factors, including injury severity and pathology location, are conceptualized as factors that increase 101 the likelihood of deficits in social cognition and atypical social interaction, while 102 environmental factors may further heighten risk or represent sources of resilience that buffer 103 against the negative long term consequences of TBI. In addition, the model posits reciprocal 104 interactions between various components of social information processing (SIP; cognitive-105 executive functions, social cognition, social problem solving), social interaction, and social 106 adjustment, such that deficits in any one component in SIP may contribute to impaired social 107 108 interaction and poor social adjustment, including EB.

In order to address limited understanding of the links between criminality and
pediatric TBI, further research is required to investigate factors that may contribute to
maladaptive or antisocial behavior among young adult survivors of pediatric TBI. In
conceptualizing EB as a marker of risk for delinquency and/or criminal behaviour, it may be
that injury-related neurocognitive impairments and environmental factors confer risk for
criminality via their influence on EB.

The objectives of the present investigation were to (1) examine the prevalence of 115 clinically significant EB problems in young adult survivors of pediatric TBI and (2) evaluate 116 the respective contributions of a variety of injury and non-injury related risk and resilience 117 factors at various time points to variability in EB outcomes 16 years after pediatric TBI. More 118 specifically, guided by the HMSC model⁴⁷, we aimed to examine relationships between long-119 term externalizing symptoms and a variety of individual and environmental factors including: 120 pre-injury individual and family functioning; injury severity and acute intellectual 121 functioning; executive functioning; and social cognitive and affective functions, including 122 social perception and pragmatic communication. 123

124	We predicted that relative to population expectations, a significantly greater
125	proportion of young adults with TBI would show clinically significant EB. Furthermore, we
126	hypothesized that more frequent EBs would be related to (a) greater injury severity; (b)
127	poorer pre-injury adaptive and family functioning; (c) poorer acute intellectual functioning;
128	(d) poorer executive function at 10-years post injury; and (e) reduced emotional perception
129	and more frequent pragmatic communication difficulty at 16-years post-TBI.
130	
131	Method
132	Participants
133	This longitudinal study followed up a sample originally recruited from consecutive
134	admissions to the emergency department at The Royal Children's Hospital, Melbourne,
134 135	admissions to the emergency department at The Royal Children's Hospital, Melbourne, Australia (RCH), between 1993 and 1997 for traumatic brain injury ⁴⁸ . Inclusion criteria for
135	Australia (RCH), between 1993 and 1997 for traumatic brain injury ⁴⁸ . Inclusion criteria for
135 136	Australia (RCH), between 1993 and 1997 for traumatic brain injury ⁴⁸ . Inclusion criteria for the original study were: (1) age at injury 1.0 to 12.0 years; (2) documented evidence of TBI,

139 injury; history of previous closed head injury; or pre-existing physical, neurological,

140 psychiatric or developmental disorder.

During the initial recruitment period, 172 children aged under 12 years were admitted 141 to hospital with a diagnosis of TBI and participated in the initial data collection. At 16 years 142 post-TBI, 66 participants could not be located, and 38 declined to participate (not interested / 143 too busy), 2 were deceased and 11 had incomplete datasets. Thus for the current paper 55 144 young adults (m age = 23.82 years; range = 16.25 - 30.58 years; SD = 3.85) from the original 145 TBI sample yielded data across the acute, 10-year and 16-year time points and were included 146 in analyses. Participating and non-participating samples were compared on demographic 147 and injury characteristics, including socio-economic status, gender, age at injury and the 148

149 length of period of altered consciousness, to examine potential biases in the 16-year follow-150 up sample, with no significant differences identified (p>.05).

151

152 <u>Measures</u>

Details of the child's medical and developmental history, and family demographic 153 information were collected at study enrolment. Severity groups were derived from a 154 combination of measures, including period of altered consciousness on the Glasgow Coma 155 Scale (GCS)⁴⁹, and presence of radiological and neurological abnormalities. This resulted in 156 157 the following groups: (i) mild TBI (n = 15): GCS on admission 13–15, no evidence of mass lesion on CT/MRI scans, and no neurologic deficits; (ii) moderate TBI (n = 29): GCS on 158 admission 9-12, and/or mass lesion or other evidence of specific injury on CT/MRI, and/or 159 160 neurological impairment; and (iii) severe TBI (n = 11): GCS on admission 3–8, and mass lesion or other evidence of specific injury on CT/MRI, and/or neurological impairment. 161

162

163 *Pre-injury*.

The Vineland Adaptive Behavior Scale (VABS)⁵⁰ provides parent report of a child's 164 level of adaptive function and was collected at time one to represent the child's pre-injury 165 functioning. The present study utilised the Total Adaptive Behavior score (M = 100, SD =166 15), and the Daily Living Skills and Socialization indexes as measures of pre-injury function. 167 Pre-injury family environment was measured using the parent-report *Family* 168 Functioning Questionnaire (FFQ) 51 . Each item was rated on a 6-point scale where 1 =169 totally agree to 6 = totally disagree. Three factors are derived from the measure: Conflict, 170 171 Intimacy and Parenting Style, with higher scores reflecting more of that characteristic. The Intimacy factor was utilised for statistical analyses because it represents a measure of family 172 cohesion 52. 173

174

175 *Acute post-injury.*

The IQ assessment employed at the acute time point varied depending on the child's 176 age. Thus *Bayley Scales of Infant Development* children aged <30 months; *Wechsler* 177 Preschool and Primary Scale of Intelligence Revised ⁵⁴ for children aged 30 months to 6.5 178 years; and Wechsler Intelligence Scale for Children - Third Edition⁵⁵ children aged >6.5 179 years were all used. Full scale IQ scores (FSIQ), were used in analyses (M = 100, SD = 15). 180 Daniel's Scale of Occupational Prestige ⁵⁶ was used as a rating of family socio-181 economic status (SES) at the acute time-point. Ratings are made on a seven-point scale 182 where a higher score denotes lower SES. 183 184 185 10 years post injury. Based on previous findings from the longitudinal study two measures of executive 186 functioning were used to explore its role in prediction of problem behaviour ⁵⁷. The *Behavior* 187 *Rating Inventory of Executive Function* (BRIEF)⁵⁸, Metacognition and Behavioral 188 Regulation index scores, and the General Executive Composite Score (M = 50, SD = 10) 189 were calculated on the basis of parent or close other ratings at the 10 year time-point. Higher 190 scores represent greater dysfunction, and scores >65 indicate functioning at a level of clinical 191 concern. 192 The 20 Questions Task from the DKEFS test (20Q)⁵⁹ was used as a direct assessment 193 of abstract reasoning as it measures abstract thinking as well as problem solving and the 194 utilization of feedback. The abstraction scaled score was used in analyses (M = 10, SD = 3). 195

196

197 *16 years post-injury.*

The Adult Behavior Checklist (ABCL)⁶⁰ consists of 126 behavior problem items that 198 are evaluated by a significant other for the preceding six months. Statements are scored on a 199 three-level rating scale ranging from not true to very true (M=50; SD=10; borderline/clinical 200 range if score >65 for the syndrome scales; >60 for the domain) with a higher score 201 indication of greater impairments. As the outcome measure in the present study, the domain 202 Externalizing Behavior was used. It comprises three syndrome scales: Rule Breaking (13 203 items; e.g., gets drunk, in trouble with law), Aggressive Behavior (16 items; e.g., mean to 204 others, threatens people) and Intrusive Behavior (6 items; e.g., brags, demands attention, 205 206 shows off). The ABCL has been proven reliable in terms of test-retest correlations and internal consistency of scales ⁶⁰, and has good inter-rater reliability for most scales ⁶¹. 207 The *Latrobe Communication Questionnaire* (LCQ)⁶² is a 30-item subjective 208 assessment that reflects the four domains Quantity, Quality, Relation and Manner of everyday 209 communication. Each item has four levels of response ranging from (1) "Never or rarely" to 210 (4) "Usually or always" with a higher score reflecting more frequent communication 211 difficulty. Data analyses employed a total score, reflecting overall communication perceived 212 by a significant other. 213

The *Advanced Clinical Solutions Social Perception subtest* (ACS) ⁶³ measures skills associated with the comprehension of social communication. It consists of three emotion perception tests yielding four scores: Affect Naming, Prosody-Faces, Prosody-Pairs, and, collectively, the Emotion Perception Total score. Age-adjusted scaled scores (<u>M</u>=10, <u>SD</u>=3) for each of these test scores were employed in analyses.

In addition, respondents were asked whether they had 'received intervention of any kind (e.g. speech and language, motor, cognitive)'. Those who stated that they had received an intervention were asked to specify the intervention through an open-ended response.

222

223 <u>Procedure</u>

The current study was approved by the Human Research Ethics Committee of RCH. 224 Melbourne, Australia. Children were enrolled in the study during their initial hospital 225 226 admission, and were evaluated at various time points: 0-3 (acute), 6, 12, and 30 months, and 5, 10 and 16-years post injury. At each wave of data collection, young people and families 227 enrolled in the original study were sent tracing letters that included a detailed description of 228 the study, and were asked to provide written informed consent, in keeping with hospital 229 ethics procedures. Neuropsychological assessments and questionnaires were administered at 230 each time point by a qualified child psychologist over a two hour period. 231 232 Data analysis 233 234 All data were entered into SPSS statistical software (Version 21.0; SPSS, Inc., Chicago, IL) and screened for violations of normality. An alpha level of p < 0.05 was used to 235 indicate significance, and effect sizes were calculated using Cohen's d. 236 The calculation of individual impairment ratings was based on the ABCL 237 Externalizing Behavior composite scale, and Chi-square tests were employed to examine the 238 proportion young adults in each severity group demonstrating impairment at 16-years post 239 injury. For the broadband scales, scores > 63 are considered clinically significant and scores 240 of 60-63 are in the borderline range for clinical significance. 241 242 Predictors of 16-year behavioral outcomes were examined using a series of regression analyses as follows; 243 (1). Preliminary univariate regressions were employed to examine relations between 244 EB and all independent variables. Variables that were unrelated to EB at this step were 245 excluded from subsequent analyses. 246 (2). Four separate multivariate adjusted regression models were employed to 247

248	investigate relationships between EB and variables related to (a) pre-injury adaptive
249	functioning; (b) injury-related factors/acute intellectual functioning; (c) executive
250	functioning/interventions at 10-years post-TBI; and (d) social cognition and communication
251	at 16-years post injury.
252	(3). Variables that remained statistically significant in each of the adjusted models
253	were entered into the final adjusted multivariate regression model.
254	
255	Results
256	3.1. Demographic and injury characteristics.
257	There were no significant differences across severity groups with respect to age at
258	16-year assessment, age-at-injury, pre-injury adaptive abilities, FSIQ, SES or family function
259	(Table 1). Groups differed on gender ($\chi^2(2, 55) = 7.51$, $p = .023$), such that there were a
260	significantly greater proportion of males in the severe TBI group than the mild and moderate
261	TBI groups. As expected, all severity groups differed for GCS-24 hours, $F(2,48) = 21.92$,
262	<i>p</i> <.001.
263	Table 1 about here
264	
265	3.2. Externalizing symptoms at 16-years post-TBI.
266	Table 2 displays the total number and proportion of TBI participants found to have clinical or
267	sub-threshold levels of externalizing symptoms. Pearson Chi Square analyses revealed no
268	significant association between externalizing symptoms and injury severity, $\chi^2(2, 55) = .20$, p
269	= .91.
270	Table 2 about here
271	
272	3.3. Predictors of ABCL Externalizing: Pre-injury adaptive functioning.

273	Unadjusted model. Preliminary univariate regression analyses revealed significant
274	relationships between ABCL Externalizing and pre-injury Vineland Adaptive Functioning
275	(p=.004), including the Daily Living Skills $(p=.040)$, and Socialization $(p=.007)$. There was
276	no significant relations between ABCL Externalizing and Vineland Communication (p =.106),
277	Family SES (p =.724) or Family Intimacy (p =.188).
278	<i>Adjusted model.</i> The multivariate adjusted model was moderately significant $F(3,45) = 3.27$,
279	p = .03, however due to high colinearity between the independent variables, there were no
280	significant individual pre-injury predictors of ABCL Externalizing (Table 3).
281	
282	Table 3 about here
283	
284	3.4. Predictors of ABCL Externalizing: Injury-related factors and acute intellectual
285	functioning.
286	Univariate regression analysis revealed a significant relation between ABCL Externalizing
287	and FSIQ Time 1, $F(1,42) = 11.80$, $p = .001$. (Table 4). There was no significant associations
288	between ABCL Externalizing and Glasgow Coma Score (GCS; $p = .491$), age at injury ($p =$
288 289	between ABCL Externalizing and Glasgow Coma Score (GCS; $p = .491$), age at injury ($p = .287$), neurological signs ($p = .363$) or surgical intervention ($p = .577$).
289	
289 290	.287), neurological signs ($p = .363$) or surgical intervention ($p = .577$).
289 290 291	.287), neurological signs ($p = .363$) or surgical intervention ($p = .577$).
289 290 291 292	.287), neurological signs ($p = .363$) or surgical intervention ($p = .577$). Table 4 about here
289 290 291 292 293	.287), neurological signs ($p = .363$) or surgical intervention ($p = .577$). Table 4 about here <u>3.5. Predictors of ABCL Externalizing: Executive functioning/interventions at 10-years post-</u>
289 290 291 292 293 294	.287), neurological signs (<i>p</i> = .363) or surgical intervention (<i>p</i> = .577). Table 4 about here <u>3.5. Predictors of ABCL Externalizing: Executive functioning/interventions at 10-years post- TBL</u>

298	ABCL Externalizing was not significantly associated with BRIEF Global Executive
299	Composite (p =.066), BRIEF Metacognition (p =.128) or access to interventions by 10-years
300	post-injury ($p = .427$).
301	<i>Adjusted model.</i> The multivariate adjusted model was moderately significant $F(2,27) = 4.90$,
302	p=.02, with BRIEF Behaviour Regulation Index the single significant predictor (Table 5).
303	
304	Table 5 about here
305	
306	3.6. Predictors of ABCL Externalizing: Socio-affective functioning.
307	Unadjusted model. Univariate regression analyses revealed significant relations between
308	ABCL Externalizing and ACS Social Perception Total Score ($p = .02$) and LCQ Proxy Report
309	(<i>p</i> <.001).
310	<i>Adjusted model.</i> The multivariate adjusted model was highly significant $F(2,39) = 10.11$,
311	p<.001, with LCQ Proxy report the single significant predictor (Table 6).
312	
313	Table 6 about here
314	
315	3.7. Predictors of ABCL Externalizing: Final adjusted model.
316	Due to high colinearity between measures of pre-injury adaptive functioning (Table
317	3), the final adjusted model evaluated the respective contributions of each pre-injury variable
318	via three separate multivariate regression models.
319	As shown in Table 7, Model 1 was highly significant, $F(4,36) = 9.03$, $p < .001$, with
320	more frequent externalizing behavior related to poorer adaptive functioning, lower FSIQ
321	(time 1) and more frequent social communication difficulty.

322	Model 2 ($F(4,36) = 9.03$, $p < .001$) and Model 3 ($F(4,38) = 9.97$, $p < .001$) were highly
323	significant. In addition to the significant predictors identified in Model 1, pre-injury daily
324	living skills and pre-injury socialization emerged as significant individual predictors of
325	externalizing outcome in Model 2 and Model 3 respectively.
326	
327	Table 7 about here
328	
329	Discussion
330	The aim of the present longitudinal prospective study was to 1) investigate rates of EB
331	in young adults with pediatric TBI; and 2) evaluate the respective contributions of a variety
332	of injury and non-injury related risk and resilience factors at various time points to variability
333	in EB outcomes 16 years after pediatric TBI.
334	There was partial support for all hypotheses. Relative to population expectations, rates
335	of EB were significantly elevated among young adult survivors of pediatric TBI. Moreover,
336	more frequent EB at 16-years post-injury was associated with poorer pre-injury adaptive
337	functioning, reduced acute intellectual functioning and poorer pragmatic communication
338	skills.
339	
340	Outcomes
341	Our results show that, by young adulthood, one of every four young people with a
342	history of pediatric TBI had developed clinical or sub-threshold levels of externalising
343	behaviour. Rates of EB in our sample compare to reported prevalence rates of 5-10% in the
344	general population ^{64,65} , indicating a heightened risk of EB in young adulthood following
345	pediatric TBI and mirroring previously identified associations between pediatric TBI and life-
346	course persistent offending behaviors ¹³ .

In keeping with the premises of the HMSC model, EB was linked to a range of pre-347 injury and post-injury risk factors, discernible in the acute, adolescent and young adult 348 phases. The contribution of pre-injury adaptive functioning to very long term social outcome 349 is consistent with previous reports ⁶⁶, and may indicate that the influence of early brain injury 350 interacts with a pre-existing vulnerability (i.e., '*double hazard theory*' ⁶⁷) to heighten risk for 351 maladaptive behavior in the very-long-term post TBI. Moreover, the relationship between EB 352 and FSIO converges with previous literature in non-clinical samples ^{68,69} to suggest that 353 higher levels of intellectual functioning may represent a source of resilience that buffers the 354 355 risk of behavioral dysfunction in the long-term post injury.

In keeping with previous research ³⁰, pragmatic communication was the strongest and 356 most significant predictor EB in young adults with pediatric TBI. The finding that poorer 357 pragmatic communication was associated with more frequent EB may be interpreted from a 358 diathesis stress perspective ⁴⁷. In line with the HMSC model, it may be that difficulty using 359 and ascribing meaning to everyday social discourse contributes to rejection or alienation by 360 interactive partners at the level of the social interaction. In this context, failure to negotiate 361 the complex demands of everyday discourse is likely to elicit distress, reflected in EBs (e.g., 362 aggression, rule breaking, intrusive conduct) which further limit the individual's capacity to 363 negotiate the normative developmental goals of young adulthood. 364

Contrary to expectations, clinical or sub-threshold levels of EB problems were not associated with injury severity but were instead equally apparent across young adults with TBI of all severity levels. This finding is counter to previous studies that link more severe TBI to elevated risk for violent offending ^{6,70} and custodial sentences ^{5,9}, and suggests that early clinical indicators of injury severity have limited prognostic utility for longer term behavioral outcomes at least where injuries are sustained during childhood, where the brain is rapidly developing and has potential for reorganization.

Moreover, while previous reports have linked EB and/or persistent offending to factors such as social disadvantage and poorer executive functioning ³²⁻³⁴, these factors did not significantly contribute to EB in the final adjusted model. While these non-significant relationships may to some extent reflect small sample size, they may also indicate that, after prolonged recovery and increasing time since injury, executive function and indices of preinjury environment become less important prognostic indicators of outcome.

378

379 Limitations

Sample. Attrition and sample bias are potential risks with this prospective,
 longitudinal study. Due to work commitments, travel distance or current life events, some
 young adult participants were not able to participate. Nevertheless, comparison of the
 participating and non-participating families indicated no systematic differences with the
 exception that the non-participant group had lower SES.

Measures. The source of information, proxy-report completed by the significant 385 (either parent or partner/close friend), may also affect the level of reported externalizing 386 symptoms. As young people become more independent, parents may be less knowledgeable 387 about the young person's psychosocial functioning. While Green et al.⁷¹ reported a fair-to-388 excellent agreement on psychosocial functioning between the adolescent with a pediatric TBI 389 and their parent, Rosema et al.⁷² showed that, during the transition into adulthood, the young 390 adult with pediatric TBI did agree with parent report on the more observable behaviors, such 391 as drug and alcohol use, social and communication skills, however, they did not concur on 392 levels of internalizing symptoms, aggressive behavior and thought problems. Therefore self-393 report as well as direct such as a structured interview is recommended to obtain a more 394 complete representation of risk and resilience factors of EBs following pediatric TBI. 395

396

397 <u>Clinical implications and future research</u>

Relative to population expectations ^{64,65}, a greater proportion of young adults with 398 TBI demonstrated clinical or sub-threshold levels of EBs, which may in turn place these 399 young people at greater risk for maladaptive behavior trajectories characterized by rule 400 breaking, anti-social behaviour and offending. These findings have implications for policy 401 implementation in the youth justice system. For example, screening and assessment for TBI 402 within youth justice services may increase understanding of factors that may lead young 403 people to offend, and assist in identifying young offenders who may benefit from relevant 404 405 interventions, such as psycho-education and rehabilitation programs that specifically target social communicative dysfunction that persists into the long-term post injury ³⁰. Surprisingly, 406 407 and in contrast to the largely medical model used to predict outcomes post-injury, injury characteristics were less important than environmental and pre-injury factors in determining 408 outcome. Environmental factors, in particular, may be seen as potentially modifiable risk 409 factors, offering an opportunity for early intervention to reduce risk of long term problems in 410 411 this group.

The heightened prevalence of clinical or sub-threshold levels of EB in our sample 412 underscores the need for provision of such early preventative interventions, as well as long 413 term follow up and psycho-education for young people with TBI. For example, initial 414 assessments in the acute and chronic stages of injury may assist to identify children 415 presenting with risk factors, such as poorer pre-injury adaptive functioning and reduced IQ, 416 and direct these children to appropriate services. An awareness of such factors should be 417 shared with primary health care providers and schools, so as to support follow-up provision 418 and further monitoring of relevant factors. This will also offer the means to provide 419 continued engagement with parents and young people regarding the potential medium and 420

421 long term impact of TBI on behavioural and functional difficulties that they may not readily422 associate with the injury.

In addition, further research is needed to identify factors that may be protective against problematic levels of externalising behaviour despite the presence of pre-injury and acute risk factors. Person-oriented, qualitative case study approaches can complement grouplevel analyses, and offer an opportunity to evaluate how injury and non-injury related risk and resilience factors may interact to contribute to externalising behaviour in young adulthood.

- 429
- 430

Conclusion

In summary, results suggest that young adults with pediatric TBI are at elevated risk for 431 externalizing trajectories characterized by aggression, rule breaking and intrusive conduct. In 432 line with the HMSC model, more frequent externalizing behaviour was linked to a range of 433 pre-and post injury risk and resilience factors, including poorer pre-injury adaptive 434 435 functioning, reduced IQ and more frequent pragmatic communication difficulty. These findings underscore the need for screening and assessment of TBI among young offenders, 436 and suggest that early and long-term targeted interventions may be required to address risk 437 factors for EBs in children and young people with TBI. 438
