Abstract

Objectives: The purpose of the present study was to test a structural model examining the interrelationships between exercise imagery, self-reported exercise behaviour and well-being in older adults.

Design: Cross-sectional survey.

Method: Participants were 499 older Greek adults (50.10% males) aged between 51 and 84 years (M age = 57.31; SD = 5.52) who completed questionnaires measuring exercise imagery use, exercise behaviour, subjective vitality, and physical self-worth. The relationship between these variables was tested with a structural model based on the applied model of imagery use for exercise (Munroe-Chandler & Gammage, 2005).

Results: Energy imagery positively predicted exercise behaviour and subjective vitality, and appearance and technique imagery positively predicted physical self-worth.

Conclusions: These results indicate older adults engage in different types of imagery to motivate themselves to exercise and improve their well-being, thus implying that the content of imagery interventions should be specifically tailored to the outcomes older adults wish to realise for interventions to be effective.

Exercise imagery and its correlates in older adults

Physical activity plays an important role in successful ageing through the prevention of chronic disease and the promotion of functional capabilities, health, and well-being (Baker, Meisner, Logan, Kungl, & Weir, 2009; Rowe & Kahn, 1987). These benefits include reduced risk for cardiovascular disease (Hamer & Chida, 2008), type 2 diabetes mellitus (Orozco et al., 2008), falling (Gillespie et al., 2003), dementia (Larson et al., 2006), and premature death (Byberg et al., 2009; Sui et al., 2007). The accumulative evidence also indicates that being active in later life lowers the cognitive and metabolic functional declines that normally accompany ageing (DiPietro, Dziura, Yeckel, & Neufer, 2006; Keysor, 2003), and enhances mental health and quality of life (Penedo & Dahn, 2005; Rejeski & Mihalko, 2001).

Despite the physical and psychological importance of being active when older, sedentary behaviour is a major public health concern for adults aged 50 years and over (Prohaska et al., 2006). This age group represents the fastest growing segment of the population and consists of those at greatest risk of chronic disease, disability and health care utilisation (King, Rejeski, & Buchner, 1998). Many older adults are not participating in sufficient exercise, with only 45.4% of Greek males and 38.2% of Greek females aged 60 years and older being regularly physically active (Pitsavos, Panagiotakos, Lentzas, & Stefanadis, 2005). Similarly, the vast proportion of older adults across a range of European countries are insufficiently physically active to accrue substantial health benefits (Besson et al., 2009). These findings underscore the need to more effectively promote physically active living in this age group and the value of interventions targeting physical activity increases and the maintenance of these behaviours.

Surprisingly, however, research rarely investigates how older adults self-regulate their exercise behaviour, motivation, and well-being. This is of particular importance since most interventions result in only modest changes in physical activity levels (Eakin, Glasgow, &

1 Riley, 2000) and many older individuals fail to maintain newly adopted exercise patterns
 2 (Ecclestone, Myers, & Paterson, 1998). Moreover, older adults have identified internal
 3 barriers including a lack of motivation as a constraint to their exercise participation (Lees,
 4 Clark, Nigg, & Newman, 2005). Self-regulation, the personal regulation of goal-directed
 5 behaviour or performance (Bandura, 1997), is an important contributor to being physically
 6 active (Umstattd, Wilcox, Saunders, Watkins, & Dowda, 2008). Personal strategies (e.g.,
 7 goal-setting, planning, self-monitoring and time management) are often incorporated into
 8 interventions, but these forms of self-regulation are rarely measured or evaluated (e.g.,
 9 Brawley, Rejeski, & Lutes, 2000; Juneau et al., 1997; Sharpe et al., 1997). The resulting lack
 10 of information makes it difficult for organisers of health-promotion programs to identify what
 11 are the effective ways of developing self-regulatory processes and, in turn, maximise the
 12 likelihood of intervention success (Ayotte, Margrett, & Hicks-Patrick, 2010).

13 Imagery is an internal experience that occurs in different sensory modalities and
 14 mimics real experience (White & Hardy, 1998). In his seminal paper, Hall (1995) proposed:
 15 1) individuals experience a diverse range of exercise images; 2) exercise images can be
 16 classed as serving cognitive or motivational functions; and 3) exercise behaviour would be
 17 influenced by experiencing these images, both directly and indirectly by raising expectations
 18 of positive outcomes (e.g., health benefits, weight management). Qualitative and quantitative
 19 research has supported these predictions and substantiated imagery as a self-regulatory
 20 strategy for increasing and/or maintaining exercise behaviour (Gammage, Hall, & Rodgers,
 21 2000; Giacobbi, Hausenblas, Fallon, & Hall, 2003; Hausenblas, Hall, Rodgers, & Munroe,
 22 1999; Kim & Giacobbi, 2009; Short, Hall, Engel, & Nigg, 2004).

23 A central finding of this research has been that exercisers use three main types of
 24 imagery: appearance (motivational function), energy (motivational function), and technique
 25 (cognitive function) (Gammage et al., 2000; Hausenblas et al., 1999; Kim & Giacobbi, 2009).

1 Appearance imagery involves imaging improvements to one's physical appearance. Energy
2 imagery includes imagery of exercising to distract/motivate as well as feel energized. Finally,
3 technique imagery refers to images of learning and performing exercises correctly. The
4 content and functions of exercisers' imagery forms the core of Munroe-Chandler and
5 Gammage's (2005) *applied model of imagery use for exercise*, which hypothesises that each
6 type of imagery will impact specific affective, cognitive and behavioural outcomes.
7 Appearance imagery has been positively associated with intention to exercise (Rodgers,
8 Munroe, & Hall, 2001). By comparison, energy imagery has been positively associated with
9 exercise-induced feeling states of revitalisation, tranquillity, and positive engagement
10 (Cumming & Stanley, 2009). Further, Cumming (2008) found that technique imagery
11 positively predicted perceptions of task efficacy (e.g., confidence in one's abilities to perform
12 elemental aspects of an exercise task, including pacing oneself and avoiding overexertion;
13 Rodgers & Sullivan, 2001).

14 Together these results provide support for the applied model of imagery use for
15 exercise and imply different types of imagery can be used to regulate exercise thoughts,
16 feelings, and behaviours (Cumming & Stanley, 2009). Noteworthy is that the majority of this
17 research has employed samples of mostly young exercisers (Gammage et al., 2000; Giacobbi
18 et al., 2005; Hausenblas et al., 1999). Only a few studies have focused on older adults, but the
19 existing research does suggest exercisers continue to use, and benefit from, the same three
20 types of imagery later in life (Kim & Giacobbi, 2009; Milne, Burke, Hall, Nederhof, &
21 Gammage, 2005; Wesch, Milne, Burke, & Hall, 2006). The present study builds on this
22 burgeoning work by investigating different correlates of exercise imagery use in older adult
23 exercisers. Of particular interest was to examine the relationships between exercise imagery,
24 self-reported exercise behaviour (expressed as metabolic equivalents or METS), and two
25 forms of well-being: physical self-worth and subjective vitality.

1 Imagery use is proposed to be a determinant of exercise behaviour (Hall, 1995;
2 Munroe-Chandler & Gammage, 2005). All three types of exercise imagery play a role in the
3 self-regulation in exercise behaviour for younger adults (Gammage et al., 2000; Giacobbi et
4 al., 2005; Hausenblas et al., 1999), but imagining oneself being fitter or leaner (i.e.,
5 appearance imagery) has emerged as the best predictor (Cumming, 2008). Not yet clear is
6 whether this same pattern will be found in older adults. Appearance is a key motive to
7 exercise, also in later life, but older adults reportedly engage in less appearance imagery than
8 younger counterparts (Milne et al., 2005; Pliner, Chaiken, & Flett, 1990; Smith & Storandt,
9 1997). Imagining feelings of being energised and psyched up (i.e., energy imagery) has
10 instead emerged as more important to older adults' exercise behaviour (Wesch et al., 2006).

11 Older adults may also benefit from using imagery by experiencing changes in
12 subjective vitality, a form of eudaimonic well-being that involves feeling alive, invigorated
13 and possessing enthusiasm and energy (Ryan & Frederick, 1997). The energy available to
14 oneself is an indicator of greater health and physical functioning (Hubley & Russell, 2009;
15 Ryan & Deci, 2008), and may also serve as a protective factor against cardiovascular disease
16 (Smart Richman, Kubzansky, Maselko, Ackerson, & Bauer, 2009). Physical activity is a
17 source of energy and more active older adults report greater subjective vitality than inactive
18 older people (Kerse, Elley, Robinson, & Arroll, 2005; Stewart et al., 2003). Younger and
19 older adults also use imagery to feel energised and alter their feeling states (Cumming &
20 Stanley, 2009; Kim & Giacobbi, 2009). Thus, a greater use of energy imagery may contribute
21 to reports of subjective vitality, both directly and indirectly via changes in exercise behaviour.

22 Older adults also experience concerns of “trying not to look old” and report a strong
23 desire to preserve or improve their appearance (Hardy & Grogan, 2009). This aspiration is
24 likely reflected by appearance imagery being the most frequently reported imagery type used
25 by older adults (Milne et al., 2005). A negative body image can adversely affect a person's

sense of well-being and quality of life as well as deter them from engaging in physical activity (McLaren, Hardy, & Kuh, 2003). Exercising, however, can also enhance physical self-worth in older adults by enabling them to feel more competent to carry out their activities and feel better about their appearance (Dionigi & Cannon, 2009; Mutrie & Davidson, 1994). Given that these changes match the content of appearance and technique imagery, it is possible that using both types of imagery might improve the valued judgments individuals make about their body, including its abilities and looks (Dionigi & Cannon, 2009).

Guided by the applied model of imagery use for exercise, the purpose of this study was to test a structural model examining the relationships between exercise imagery, self-reported exercise behaviour and well-being (subjective vitality and physical self-worth). Based on the extant literature, we hypothesised a direct relationship between the exercise imagery types (energy, technique, and appearance) and self-reported exercise behaviour. A direct relationship, as well as an indirect relationship via exercise behaviour, was also predicted between energy imagery and subjective vitality, technique imagery and physical self-worth, and appearance imagery and physical self-worth.

Method

Participants

Participants were 499 community-dwelling Greek adults (50.10% males) aged between 51 and 84 years (M age = 57.31; SD = 5.52). All participants reported engaging in at least thirty minutes of moderate intensity (physical activity that make people slightly out of breath) or strenuous exercise on a weekly basis. Most of the participants were married (70.90%). Based on self-reported height and weight measures, Body Mass Index (BMI) was estimated at 26.15 (SD = 3.63).

Measures

1 **Exercise imagery.** The Exercise Imagery Questionnaire (Hausenblas et al., 1999) was
 2 adopted as a measure of exercise imagery. Three imagery factors, each containing three
 3 items, were examined: energy (*e.g.*, to keep me going during the day, I imagine exercising),
 4 appearance (*e.g.*, I imagine a “firmer me” from exercising) and technique (*e.g.*, “when I think
 5 about exercising, I imagine doing the required movements”). The participants were provided
 6 with a description of imagery and then asked how often they generally use the different
 7 images. Each item is measured on a scale ranging from 1 (*never/rarely*) to 9 (*always*).
 8 Good psychometric properties, including internal reliability coefficients, test-retest reliability
 9 and concurrent validity, have been reported for this scale (Hausenblas et al., 1999). Milne et
 10 al. (2005) and Wesch et al. (2006) have both reported acceptable levels of internal reliability
 11 when the EIQ has been administered to older adults.

12 **Exercise behaviour.** Godin and Shephard's (1985) leisure-time exercise
 13 questionnaire was used as a measure of exercise behaviour during a typical week.
 14 Participants were asked to report how often (*i.e.*, frequency) they engaged in mild, moderate
 15 and strenuous exercise for 20 minutes or more during a typical week. Examples of mild,
 16 moderate and strenuous physical activities were provided to the participants. A total exercise
 17 score in metabolic equivalents (METs) was derived by weighting the frequency of mild,
 18 moderate and strenuous activities by their respective MET values (*mild* = 3, *moderate* = 5,
 19 *strenuous* = 9). Jacobs, Ainsworth, Hartman, and Leon (1993) reported this scale as reliable
 20 and as possessing good concurrent validity when compared to various objective activity
 21 monitors and fitness indices.

22 **Subjective vitality.** The Subjective Vitality Scale (Ryan & Frederick, 1997) was used
 23 as a measure of the degree to which participants felt they had energy available to the self.
 24 The scale consists of seven items designed to tap feelings of energy and aliveness in general
 25 (trait). A seven point anchor response scale was used (1 = *not at all true*; 7 = *very true*).

The scale has demonstrated high internal reliability and evidence of support for its concurrent validity has been reported in previous research (Ryan & Frederick, 1997).

Physical self-worth. This variable was measured using an adapted version of the physical self-worth subscale (6 items) from the Physical Self-Perception Profile (PSPP; Fox & Corbin, 1989). Although the scale was originally set out as a forced-choice structured alternative format (with the provision of two alternative statements about what a person think they might be like), we decided to adapt the scale using a format similar to the other variables measured in the present study. This approach has previously been used by other researchers employing the PSPP in research using older adults (e.g., McAuley, Elavsky, Motl, Konopack, Hu, & Marquez, 2005). An example item from the physical self-worth sub-scale is “I have a good feeling about myself physically” and in this adapted version, the response scale ranged from 1 (= *never*) to 4 (= *always*). Good psychometric properties of the scale, with regard to internal reliability (McAuley et al., 2005; Sonstroem, Harlow, & Josephs, 1994; Sonstroem, Speliotis, & Fava, 1992) and test-retest reliability (Fox & Corbin), have been reported in previous research.

Procedures

Prior to study commencement, ethical approval was sought from an ethics review panel at a Greek University. All scales were translated from English to Greek and backwards by a team of three bilingual university professors. When consensus on the item content was reached, the questionnaires were distributed, and supervised, by trained research assistants to older adults in social clubs for the elderly which is a common meeting place for older adults in Greece. All these clubs were based in and around Athens, Greece. With permission of managers of the clubs, the research assistants approached older adults, briefly explained the purpose of the study and asked whether they engaged in regular weekly exercise (i.e., structured physical activity that make individuals slightly out of breath at least once per week

for at least 20 minutes duration). Once eligible potential participants verbally agreed to take part, they were asked to sign informed consent forms and were reassured that the responses to the questionnaires would remain anonymous and confidential. The research assistants supervised the completion of the questionnaires and were available for questions if needed.

Data analysis

Prior to the main analyses, we calculated Cronbach's alpha coefficients and descriptive statistics for all scales used in the study. We also ran a MANOVA analysis to test for possible gender differences in the variables of interest. To test the hypothesised model of interrelationships between the variables in the model, we used structural equation modelling (SEM) analysis using the EQS software (version 6.1; Bentler, 2003) to perform the analysis. We employed the robust maximum likelihood estimation method because the normalised estimate of Mardia's coefficient was 39.43, indicating departure from multivariate normality.

Results

Descriptive Statistics and Preliminary Analyses

All scales demonstrated adequate internal reliability (range $\alpha = .72 - .84$) with one scale displaying marginal reliability (physical self-worth: $\alpha = .67$). However, because of the centrality of the construct within the main model we retained this scale.

The means and standard deviations of the key variables used in the study are displayed in Table 1. Table 1 illustrates that all three imagery functions were used to a moderate degree and that appearance imagery was the most commonly adopted form of imagery.

With regard to gender differences, a MANOVA test revealed no significant differences in any of the imagery types (Pillai's Trace = .005; $F(1,487) = .75$; $p = .53$; *partial* $\eta^2 = .005$). Further, independent samples t-tests revealed no significant differences in exercise behaviour ($t(497) = 1.37$; $p = .17$), subjective vitality ($t(496) = .20$; $p = .85$) or physical self-worth

($t(497) = .72; p = .47$) between the gender groups. Therefore, we did not consider gender any further.

Testing the Hypothesised Model

Structural equation modelling was used to model the direct and indirect relationships between the imagery functions, exercise behaviour and the well-being outcomes. Exercise behaviour (METS) was an observed variable in the model. All other constructs in the model were tested as latent factors. The latent constructs of energy, technique and appearance imagery were indexed by their individual sub-scale items. The three imagery factors were inter-correlated. Subjective vitality and physical self-worth were indexed by three indicators (or 'parcels') each. These parcels represent unweighted average scores which are created by pairing up items with the strongest loadings with items with weaker loadings from the same scale (Little, Cunningham, Shahar, & Widaman, 2002). Parcelling is appropriate to use as a means of increasing the stability of parameter estimates and retaining an acceptable ratio of sample size to estimated parameters in studies which consist of relatively small sample sizes (Bandalos & Finney, 2001).

The hypothesised model is presented in Figure 1. The solution converged, producing good fit indices (see Hu & Bentler, 1999): Robust $\chi^2(93) = 208.10, p < .01$; robust NNFI = .94, robust CFI = .95, robust RMSEA = .05, SRMR = .05. However, some of the parameters in the model were not significant. As shown in Figure 1, only energy imagery significantly predicted exercise behaviour, while all three imagery types directly predicted the well-being outcomes. Exercise behaviour significantly predicted subjective vitality and physical self-worth. The indirect effects between energy imagery and subjective vitality ($\beta = .04$) and between energy imagery and physical self-worth ($\beta = .04$) were not significant (i.e., $p > .05$).

Discussion

1 The present study tested the relationships between exercise imagery, self-reported
2 exercise behaviour and well-being (subjective vitality and physical self-worth). Consonant
3 with the applied model of imagery use for exercise (Munroe-Chandler & Gammage, 2005),
4 we hypothesised a direct relationship between three main types of exercise imagery (energy,
5 technique, and appearance) and self-reported exercise behaviour. A direct relationship, as
6 well as an indirect relationship via exercise behaviour, was also predicted between energy
7 imagery and subjective vitality, between technique imagery and physical self-worth, and
8 between appearance imagery and physical self-worth.

9 In partial support of our hypotheses, older adults' use of energy imagery was directly
10 related to their self-reported exercise behaviour, but appearance and technique imagery were
11 not significant predictors. Qualitative studies and correlational analyses have previously
12 implicated all three types of exercise imagery in the self-regulation of younger adults'
13 exercise behaviour, but appearance imagery has been reported to be the best predictor
14 (Cumming, 2008; Gammage et al., 2000; Giacobbi et al., 2005; Hausenblas et al., 1999).
15 Indicating the need to consider the participants' age in research of this kind, a different pattern
16 of relationships emerged for older adults in the present study. Rather than images of how
17 one's body looks playing an important role in motivating older adults to exercise, it was
18 instead images of feeling energised. This finding is not altogether surprising because adults
19 aged 50 years and over interviewed by Hardy and Grogan (2009) described how the
20 experience of elevated mood and increased energy encouraged them to adhere to exercise.

21 Wesch et al. (2006) also reported energy imagery to be the strongest predictor of
22 barrier efficacy (i.e., confidence in one's ability to perform a task under challenging
23 conditions or to overcome social, personal, and environmental constraints) and scheduling
24 efficacy (i.e., the confidence in one's ability to schedule or plan strategies for carrying out a
25 specific action). According to Bandura's (1997) social cognitive theory, increases in these

1 efficacy expectations would lead older adults to have a greater belief in their abilities to
2 successfully carry out behaviours that support their exercise routine, and these beliefs would
3 result in higher physical activity levels. Furthermore, Hall, Rodgers, Wilson, and Norman
4 (2010) recently found energy (and technique) imagery to be more strongly associated with
5 self-determined motivation than appearance imagery in individuals between the ages of 25
6 and 65 years. The authors' interpretation of this finding was formed on the tenets of self-
7 determination theory (Deci & Ryan, 2000), and led them to propose that better quality of
8 motivation (i.e., more autonomous or self-determined) would result from using energy and
9 technique imagery because these types of imagery are inherent to the actual performance of
10 exercise behaviour. By comparison, appearance imagery reflects an outcome separable from
11 the exercise and is associated with less self-determined reasons for exercising. Thus,
12 converging evidence, including the findings of the present study, point to the importance of
13 encouraging older adults to image themselves energized from exercising as a way to regulate
14 their exercise behaviour and the cognitions that further support this behaviour (e.g., self-
15 efficacy beliefs and motivational regulations).

16 As expected, a direct relationship between energy imagery and subjective vitality was
17 found. However, the hypothesised indirect relationship through exercise behaviour was not
18 supported. Stanley and Cumming (2010) previously found that imaging oneself feeling very
19 energized while cycling led to increased revitalization and enjoyment in undergraduate
20 students during, and after, an acute bout of moderate exercise. Furthermore, Cumming and
21 Stanley (2009) reported energy imagery was the best predictor of exercise feeling states in
22 active individuals. The present study indicates that older adults also benefit from using
23 energy imagery by experiencing increased well-being in the form of subjective vitality.
24 Although only in partial support of our predictions, the direct nature of the relationship helps
25 to shed light on the potential mechanism by which energy imagery might positively influence

1 feelings of vitality (Ryan & Frederick, 1997). Drawing from Lang's bioinformational theory
2 (1977, 1979), energy imagery likely contains information about the physical and emotional
3 responses (i.e., response propositions) individuals would like to feel in association with a
4 particular situation, such as exercise, or more generally in their everyday lives. Vividly
5 experiencing these responses through imagery would better enable individuals to recognise
6 and/or experience them in real life (Cumming & Stanley, 2009). For this reason, energy
7 imagery is recommended as a way to improve exercise-related affect and feeling states (e.g.,
8 Cumming & Stanley, 2009; Munroe-Chandler & Gammage, 2005; Stanley & Cumming,
9 2010). In the case of older adults, our findings suggest this recommendation can also be
10 extended to subjective vitality.

11 Also in line with our hypotheses, appearance and technique imagery were significant
12 predictors of physical self-worth. Again, however, this relationship was direct rather than
13 indirect through exercise behaviour. Being physically active is considered to improve older
14 adults' physical self-worth by enabling them to feel more satisfied with their appearance and
15 proficient in their exercise abilities (Dionigi & Cannon, 2009; Mutrie & Davidson, 1994). In
16 turn, changes in how people value their body can subsequently enhance global self-esteem
17 and thus overall mental health, as well as decrease the internal barriers perceived by older
18 adults to impair their motivation to exercise (Fox, 2000a; Lees et al., 2005). Fox (2000b)
19 suggested that positive perceptions of body image and physical competence might result from
20 simply feeling improvements in one's body as a result of exercising, regardless of whether
21 any improvements actually occur. This is also in line with Hall's (1995) original explanation
22 for why imagery might benefit exercisers; more specifically, to help them raise expectations
23 of positive outcomes. In support of these viewpoints, our findings indicate that older adults
24 who are able to mentally experience desired improvements through imagery report greater
25 physical self-worth.

1 We used a composite score to test the relationships, but it is possible that appearance
2 and technique imagery might contribute to different aspects of physical self-worth. For
3 example, imaging one's appearance might lead to greater body satisfaction whereas imaging
4 oneself correctly executing exercises might support perceptions of strength or functional
5 competence (for a discussion on the different components of physical self-worth specific to
6 older adults, see Dionigi & Cannon, 2009). If this finding was established in future research,
7 it would have important implications for how imagery interventions are designed to improve
8 physical self-worth. For an imagery intervention to be effective, the imaged content should
9 specifically target what individuals wish to change about themselves. An older adult desiring
10 to maintain, or improve, his/her ability to exercise, for example, will more likely benefit from
11 technique imagery than appearance imagery.

12 Relationships between self-reported exercise behaviour and well-being were found in
13 the present study that was also consistent with previous research. Older adults who were
14 more physically active in their leisure time reported greater subjective vitality and physical
15 self-worth. This not only strengthens advice for using physical activity as a source of energy
16 in older adults, but to also improve how they value their body (Dionigi & Cannon, 2009;
17 Kerse et al., 2005; Stewart et al., 2003). The greater well-being produced can in turn lead to
18 important changes in the mental and physical health of individuals who are otherwise at high
19 risk for chronic disease and disability (King et al., 1998). Notably, however, a stronger link
20 was found between imagery and well-being than between exercise behaviour and well-being.
21 This finding was unexpected and might be explained by how exercise imagery use was
22 measured. Although the EIQ describes individuals imaging how their appearance, energy,
23 and technique change as a result of exercising (Hausenblas et al., 1999), these images can also
24 apply to everyday situations (e.g., EIQ item #1 "To keep me going during the day, I imagine
25 exercising"). It is possible that older adults considered different situations when making their

1 ratings and this led to imagery being a better predictor of well-being than exercise behaviour.
2 This may also explain why our predicted indirect relationships via exercise behaviour were
3 not found. Whilst an older adult's exercise behaviour might not explain this relationship, the
4 applied model of imagery use for exercise points to self-efficacy beliefs as a variable to
5 consider in the future. Munroe-Chandler and Gammage (2005) suggest that different forms of
6 self-efficacy beliefs might at least partially mediate the relationship between imagery and
7 outcomes such as subjective vitality and physical self-worth, and exercise frequency might
8 moderate these effects. Hence, further testing of the model with both younger and older
9 exercisers is warranted with added variables such as self-efficacy.

10 Another possibility is that other types of imagery not measured by EIQ might be more
11 suitable for exploring the indirect relationships. The EIQ was developed to measure three
12 types of exercise imagery in younger adults and may not fully capture the corresponding
13 content for older participants. Indeed, there are likely more than three types of imagery
14 relevant to older adults. Kim and Giacobbi (2009) reported that older adults also engage in
15 confidence-enhancing images and planning/strategy images related to exercising. The revised
16 version of the Exercise Imagery Inventory (EII-R; Giacobbi, Tuccitto, Buman, & Munroe-
17 Chandler, 2010) measures these imagery types (termed exercise self-efficacy and exercise
18 routines imagery respectively) alongside exercise technique, exercise appearance/health, and
19 exercise feelings imagery. Future research should therefore examine the validity and
20 reliability of the EII-R with older adults, as well as explore the suitability of other emerging
21 imagery types (e.g., enjoyment imagery; Stanley & Cumming, 2010).

22 Further, reports of exercise frequency as measured by the LTEQ only tell us how
23 much older adults are exercising at a particular intensity (mild, moderate, and strenuous), and
24 this information does not capture the quality of their exercise experience. When it comes to
25 well-being effects it is likely that it is the quality, not just the quantity, of the exercise

1 experience that matters. An individual might exercise often, but if the exercise is done for
2 external, controlling reasons (i.e., less self-determined motivation) it may hamper the usual
3 well-being effects that occur from being physically active (Deci & Ryan, 2000). In addition
4 to self-report exercise behaviour being a crude measure of frequency and intensity, it might
5 also be affected by memory decay and social desirability biases (e.g., participants reporting
6 how much exercise they think they should be doing rather than how much they actually do).
7 Including more objective and accurate measures of physical activity, such as accelerometers,
8 as well as questionnaires to assess the quality of the exercise experience would be a valuable
9 step for exercise imagery research.

10 Despite these limitations and the cross-sectional nature of the research, the findings of
11 the present study further advance the literature by providing support for the applied model of
12 imagery use for exercise (Munroe-Chandler & Gammage, 2005) in older adults. In line with
13 the model's basic premise, each type of imagery was directly associated with conceptually-
14 related outcomes. Extending beyond the outcomes outlined in the model and those measured
15 in previous studies (e.g., Cumming, 2008; Cumming & Stanley, 2009; Hall et al., 2010;
16 Wesch et al., 2006), our study is the first to demonstrate a relationship between imagery use in
17 older adults and two forms of well-being (subjective vitality and physical self-worth). We
18 also provide evidence to further support the importance of energy imagery in promoting self-
19 regulation of exercise behaviour. Because the pattern of relationships found seems to vary
20 between younger and older adult samples, our results also support the inclusion of age as a
21 moderating variable in the model. Thus, research with older adults should re-examine
22 relationships already established with younger samples between exercise imagery use and
23 outcomes, such as self-determined motivation and feeling states. Further, there are
24 overlooked aspects of the model that still need to be considered, particularly the moderating
25 factors of an individuals' imagery ability, activity type, and physical health status. These

1 potential moderators seem particularly pertinent to consider with older adult samples. For
2 example, someone with diminished capacities might use imagery differently from a healthy
3 individual. If so, these differences would have implications for how imagery interventions are
4 designed for frail individuals or clinical populations such as those receiving treatment for
5 cancer.

6 In conclusion, relationships were found between types of exercise imagery, exercise
7 behaviour, and well-being that lay the foundation for imagery interventions with older adults.
8 Such interventions would be inexpensive and easy to implement, but few have been
9 conducted to date. A logical, and necessary, step forward for the exercise imagery literature
10 would be test the relationships emerging in the present study with a field-based imagery
11 intervention aimed at improving older adults' exercise behaviour and well-being. In doing so,
12 the ensuing information would enable organisers of health-promotion programmes to more
13 effectively develop self-regulatory processes and, in turn, improve physical activity rates in
14 our ageing population.

Table 1.

Descriptive Statistics for all Variables

Variable (range)	<i>M</i>	<i>SD</i>
1. Exercise (METS)	29.30	19.79
2. Energy imagery (1-9)	4.59	2.34
3. Appearance imagery (1-9)	5.39	1.95
4. Technique imagery (1-9)	5.20	1.90
5. Subjective vitality (1-7)	4.69	1.20
6. Physical self-worth (1-4)	2.66	.57

Note. * = $p < .05$; ** = $p < .01$

Figure 1.

Modelling the hypothesized relationships between exercise imagery, exercise behaviour (METS) and well-being outcomes

Note. The two dotted lines indicate non-significant (at $p > .05$) parameters. Ovals indicate latent factors and the rectangle represent an observed variable.
