40 **Translational relevance**

41

42 Myeloma is a heterogeneous malignancy with disease in different subgroups of
43 patients driven by abnormalities in multiple genes and/or molecular pathways.
44 Treatment options and outcomes have improved over the last decade but novel
45 approaches are still required. In this article we use whole-exome sequencing results
46 from 463 presenting cases entered into the UK Myeloma XI study, and targeted
47 sequencing of 156 previously treated cases, to report the wide spectrum of
48 mutations in genes encoding epigenetic modifiers in myeloma. Using linked survival
49 data from the large Myeloma XI study we identify lesions that may have prognostic
50 significance in *KDM6A* and genes encoding DNA modifiers. We demonstrate an
51 increase in the frequency of epigenetic modifier mutations of certain classes as
52 disease progresses. Our analysis is particularly important as numerous mutations
53 identified suggest potential targeted treatment strategies with agents either currently
54 available or known to be in development, highlighting novel treatment approaches for
55 patients.

56

57 **Abstract**

58

59 Purpose: Epigenetic dysregulation is known to be an important contributor to
60 myeloma pathogenesis but, unlike in other B cell malignancies, the full spectrum of
61 somatic mutations in epigenetic modifiers has not been previously reported. We
62 sought to address this using results from whole-exome sequencing in the context of
63 a large prospective clinical trial of newly diagnosed patients and targeted sequencing
64 in a cohort of previously treated patients for comparison.

65 Experimental Design: Whole-exome sequencing analysis of 463 presenting
66 myeloma cases entered in the UK NCRI Myeloma XI study and targeted sequencing
67 analysis of 156 previously treated cases from the University of Arkansas for Medical
68 Sciences. We correlated the presence of mutations with clinical outcome from
69 diagnosis and compared the mutations found at diagnosis with later stages of
70 disease.

71 Results: In diagnostic myeloma patient samples we identify significant mutations in
72 genes encoding the histone 1 linker protein, previously identified in other B-cell
73 malignancies. Our data suggest an adverse prognostic impact from the presence of
74 lesions in genes encoding DNA methylation modifiers and the histone demethylase
75 *KDM6A/UTX*. The frequency of mutations in epigenetic modifiers appears to
76 increase following treatment most notably in genes encoding histone
77 methyltransferases and DNA methylation modifiers.

78 Conclusions: Numerous mutations identified raise the possibility of targeted
79 treatment strategies for patients either at diagnosis or relapse supporting the use of
80 sequencing-based diagnostics in myeloma to help guide therapy as more epigenetic
81 targeted agents become available.

82 Introduction

83

84 Myeloma is a malignancy of plasma cells, terminally differentiated B cells involved in
85 the immune response. Despite advances in therapy over the last 10 years
86 subgroups of patients diagnosed with myeloma continue to have poor outcomes and
87 most inevitably relapse. A better understanding of the genetic and epigenetic
88 abnormalities that contribute to disease pathogenesis is required in order to develop
89 new targeted treatment strategies.

90 The myeloma clone is thought to be immortalised following the acquisition of a
91 translocation into the immunoglobulin heavy chain locus (t(4;14), t(6;14), t(11;14),
92 t(14;16) and t(14;20)) or hyperdiploidy. The clone then evolves via the subsequent
93 gain of further genetic or epigenetic events.(1) Epigenetic dysregulation is known to
94 be an important contributor to myeloma progression, but the full extent of its role in
95 the pathogenesis of disease and high risk behaviour is uncertain.(2) A key example
96 of the relevance and role of epigenetic deregulation in myeloma comes from our
97 understanding of the subgroup of patients with the t(4;14), which results in the
98 juxtaposition of *MMSET*, a H3K36 methyltransferase, to the immunoglobulin heavy
99 chain locus enhancer. The resulting overexpression of *MMSET* leads to a histone
100 methylation pattern, characterised by increased H3K36me2 and decreased
101 H3K27me3, along with a distinct and aberrant DNA methylation pattern.(3)
102 Downstream events occurring as a result of this primary event include changes in
103 expression of genes involved in the cell cycle, apoptosis and cell adhesion.(4-7)
104 Patients carrying the t(4;14), around 15% of myeloma cases at clinical diagnosis(8,
105 9), tend to respond to treatment but relapse early and have a shorter overall survival,

106 though since the use of proteasome inhibition there is evidence that this poor
107 prognosis is ameliorated.

108 The impact of mutation on epigenetic modifiers in myeloma has also been reported,
109 with inactivation of the histone demethylase, *KDM6A/UTX*, seen in 10% of samples
110 (10), and mutations affecting the histone methyltransferase, *MLL*(11) the best
111 documented. The recognition of mutations in *MLL* followed the first sequencing
112 study of myeloma patients where expression of the homeobox protein, *HOX9A*, was
113 suggested to be regulated by *MLL*.(11) More recently an activating mutation of
114 *MMSET* at E1099K was found in the MM.1S myeloma cell line with the same
115 downstream effect as *MMSET* overexpression due to the t(4;14). (12)

116 Based on these considerations we sought to investigate the role of mutations in
117 epigenetic modifiers in myeloma and how such mutations might contribute to disease
118 pathogenesis. We used whole exome sequencing to examine the spectrum of
119 mutations in epigenetic modifiers in a series of 463 newly diagnosed patients
120 uniformly treated as part of the UK NCRI Myeloma XI clinical trial (MyXI) and
121 describe the clinical implication of mutations in terms of their effect on progression-
122 free and overall survival. Previously reported results from this dataset identified 15
123 significantly mutated genes in myeloma, a distinct APOBEC signature associated
124 with maf translocations and the link between these factors and prognosis.(13, 14)
125 Here we extend these analyses with a focus on highlighting epigenetic mutations
126 important in the pathogenesis of myeloma and compare the frequency of mutations
127 at diagnosis to later stages of disease, using a dataset from the University of
128 Arkansas for Medical Sciences (UAMS). This analysis comprises the largest series
129 of newly diagnosed myeloma patients sequenced to date and provides important

130 insights into the role of epigenetics in the disease, as well as highlighting potential
131 avenues for future research and targeted treatment development.

132 **Materials and Methods**

133

134 **Whole exome sequencing at diagnosis – Myeloma XI**

135 Methods used for the analysis of patient material have been previously published
136 (13, 14) but are summarised below:

137 Samples were taken, following informed consent and prior to treatment
138 commencement, from 463 patients newly diagnosed with symptomatic myeloma and
139 enrolled in the UK NCRI Myeloma XI trial (NCT01554852). The study was approved
140 by the NHS Health Research Authority, National Research Ethics Service Committee
141 and by local review committees at all participating centres. The study randomised
142 patients between triplet immunomodulatory drug (IMiD) inductions with thalidomide
143 vs lenalidomide, prior to subsequent randomisations comparing consolidation and
144 maintenance approaches. The demographics of the patients included in this
145 analysis have been published and are reproduced in **Supplementary Table 1**. (14)
146 Progression-free (PFS) and overall survival (OS), measured from initial
147 randomisation, had median follow up of 25 months, 95% CI [24.3,26.2]. The median
148 PFS was 26.6 months, 95%CI [23.6,29.9] and the median OS was not reached but
149 the 3 year OS was 66%, 95%CI [60,73].

150 CD138+ plasma cells were isolated from bone marrow cells using MACSorting
151 (Miltenyi Biotech, Bisley, UK), lysed in RLT+ buffer and DNA/RNA extracted using
152 the AllPrep kit (Qiagen, Manchester, UK). White blood cells were isolated from

153 peripheral blood, purified by Ficoll-Pacque and DNA extracted using the QIAamp
154 DNA mini kit (Qiagen).

155 DNA from both tumour and peripheral blood samples was used in the exome capture
156 protocol.(13, 15) RNA baits were designed against the human exome with additional
157 custom baits tiling the IGH, IGK, IGL and MYC loci to detect the major
158 translocations. Four exome samples were pooled and run on one lane of a HiSeq
159 2000 (Illumina, Hinxton, UK) using 76-bp paired end reads. Data quality and metrics
160 processing, processes for somatic mutation calling and molecular and copy number
161 assessments are described fully elsewhere(13).

162

163 **Copy Number Estimation and Cancer Clonal Fraction – Myeloma XI**

164 Copy number across the exome was determined using Control-FREEC(16) utilizing
165 500bp bins, each overlapping with the subsequent and previous 250bp. A minimum
166 average read depth of 50 was required in the control samples, with at least two
167 neighbouring bins required to show CN aberration to call a region as gained or lost.
168 Copy number profiles for a series of 26 chromosomal regions were compared with
169 copy number values previously estimated by multiplex-ligated probe amplification
170 tests.(17) To ensure a reliable estimation of copy number, only cases with an F
171 correlation above 50% were used for subsequent analyses (370/463).

172 Cancer clonal fraction was calculated, (18) as the proportion of tumour cells
173 containing an SNV using the equation:

$$CCF = \min\left(1, \frac{CN.r}{R}\right)$$

174 Where CCF=cancer clonal fraction (proportion of cells containing the mutation),
175 CN=copy number at that site, r=number of reads containing the mutation at that site,
176 R=total number of reads at that site.

177 **Further data analysis – Myeloma XI**

178 Lists of epigenetic modifiers were curated using database searches and previous
179 publications (**Supplementary Table 2**) with genes divided into eight classes:
180 Core/linker histones (n=79), histone demethylases (n=21), histone
181 methyltransferases (n=40), histone deacetylases (n=20), histone acetyltransferases
182 (n=25), DNA modifiers (n=8), readers (n=17) and chromatin assembly/remodelling
183 (n=46). These lists were used to interrogate the results of the sequencing analysis in
184 order to calculate the percentage of patients with a mutation in each gene and in
185 each class.

186 For all genes mutated in more than 1% of patients, mutations were mapped to the
187 relevant regions of the protein using Protein Paint (19) and the Catalogue of Somatic
188 Mutations in Cancer (COSMIC) database was searched to look for previously
189 identified variants at the same amino acid residue in other tumours.(20) Multiple
190 sequence alignment of histone 1 genes was performed by inputting sequences from
191 FASTA files obtained from uniprot.org into ClustalW2. Mutations were annotated in
192 GeneDoc. The likely effect of mutations was assessed using SIFT analysis. (21)

193 Deletions in *KDM6A* were identified using an algorithm to detect deletion of whole
194 exons (windows defined as the regions used in the Agilent exome capture). This
195 was done by comparing the read depth between the tumour and normal samples.
196 The mean depth across the window was required to be > 0.2 of the median depth in
197 the normal sample and < 0.06 in the tumour sample, with the normal value being at

198 least 8x greater than the tumour value. Positive findings using this method were
199 confirmed or excluded following visualisation in Integrated Genome Viewer (IGV).

200 Survival curves were plotted (Kaplan-Meier) and the statistical significance of the
201 difference between curves tested using the Logrank test, with $P < 0.05$ taken as the
202 level of significance. Multivariate analysis was performed using the cox-regression
203 model inputting the epigenetic mutations with a significant impact on survival by
204 univariate Logrank statistic and other standard clinical factors known to influence
205 survival in myeloma patients.

206 **Targeted sequencing in previously treated patients – UAMS**

207 156 patients who had previously undergone treatment had bone marrow samples
208 taken and genomic profiling (FoundationOne Heme[®]; Foundation Medicine)
209 performed as part of their disease reassessment work-up. Review of this data was
210 approved by the UAMS institutional review board. The demographics of the patients
211 included in this analysis are shown **Supplementary Table 3**. CD138+ cells were
212 isolated from bone marrow aspirates as previously (22) with DNA and RNA extracted
213 using the Puregene and RNeasy kits (Qiagen) respectively. Samples were submitted
214 to a CLIA-certified, New York State and CAP-accredited laboratory (Foundation
215 Medicine, Cambridge MA) for NGS-based genomic profiling. Hybridization capture
216 was applied to ≥ 50 ng of extracted DNA or RNA for 405 cancer related genes and
217 select intronic regions from 31 genes (FoundationOne Heme DNA only, n=405);
218 targeted RNA-seq for rearrangement analysis was performed for 265 genes
219 frequently rearranged in cancer. Sequencing of captured libraries was performed
220 (Illumina HiSeq 2500) to a median exon coverage depth of >250 x, and resultant
221 sequences were analyzed for base substitutions, insertions, deletions, copy number

222 alterations (focal amplifications and homozygous deletions) and select gene fusions,
223 as previously described.(23, 24) To maximize mutation-detection accuracy
224 (sensitivity and specificity) in impure clinical specimens, the test was previously
225 optimized and validated to detect base substitutions at a $\geq 5\%$ mutant allele
226 frequency (MAF) and indels with a $\geq 10\%$ MAF with $\geq 99\%$ accuracy.(23, 24) The
227 mutations reported on the F1 test were all manually, individually reviewed.
228 Mutations were retained and included in the subsequent analysis only if either they
229 were classified by Foundation Medicine as definitely 'known', were frameshift,
230 nonsense or splice-site mutations or if a mutation affecting the same amino acid
231 residue had been previously recognised in another tumour (determined by analysis
232 of Catalogue of Somatic Mutations in Cancer (COSMIC) datasets directly (20) and
233 via visualisation using the St Jude's PeCan data portal. (25))

234 Due to the greater depth of the FoundationOne Heme[®] test a cut off for mutations
235 being present in $\geq 5\%$ reads was applied to this dataset (mutations that could have
236 been detected using the depth achieved in the MyXI study). Epigenetic genes from
237 the list in **Supplementary Table 2** (and analysed in the MyXI data) which were also
238 sequenced in the UAMS dataset are shown in **Supplementary Table 4**. This
239 comprises: Core/linker histones (n=12), histone demethylases (n=5), histone
240 methyltransferases (n=11), histone deacetylases (n=3), histone acetyltransferases
241 (n=4), DNA modifiers (n=4), readers (n=2) and chromatin assembly/remodelling
242 (n=9).

243 The percentage of patients with mutations in each class of epigenetic modifier were
244 compared between the MyXI dataset and the UAMS dataset using the z-test,
245 multiple testing was corrected for using the Bonferroni method. Since CCF could not
246 be calculated for the patients in the UAMS dataset (due to the absence of copy

247 number data) the variant allele frequencies were compared for those genes with at
248 least 2 mutated samples in both datasets.

249 Results

250

251 Whole exome sequencing was performed on samples from 463 patients in the
252 Myeloma XI trial prior to treatment. We identified mutations in genes encoding
253 epigenetic modifiers in over half (53%) of patients. 20 epigenetic modifier genes
254 were mutated in at least 5/463 (>1%) of individuals with frequencies shown in **Table**
255 **1**, cancer clonal fraction (CCF), shown in **Figure 1** and mutation location annotated
256 in **Figure 2 and Supplementary Figure 1**. The distribution of the main translocation
257 subgroups, known to drive myeloma pathogenesis, did not differ significantly
258 between patients with and without a mutation in any epigenetic modifier
259 (**Supplementary Figure 2**).

260 Below we report a detailed analysis of the frequency and potential clinical impact of
261 mutations in each class of epigenetic modifier.

262 Core and linker histone mutations: HIST1H1E is significantly mutated at myeloma 263 diagnosis

264

265 The gene *HIST1H1E*, which encodes a linker histone H1 protein, was found to be
266 significantly mutated in the MyXI cohort(14) at diagnosis with mutations in 2.8% of
267 patients (13/463, $p < 1 \times 10^{-10}$, $q < 1 \times 10^{-10}$). Further analysis revealed recurrent non-
268 synonymous mutations in other histone 1 family genes including *HIST1H1B* (0.2%,
269 1/463), *HIST1H1C* (2.6%, 12/463), and *HIST1H1D* (0.6%, 3/463) with mutations in at
270 least one of these genes (*HIST1H1B-E*) occurring in 6% (28/463) of patients. The
271 mutations (**Figure 2a**) in these genes were predominantly missense SNVs affecting
272 the globular domain of histone H1. *HIST1H1B-E* were aligned (**Figure 2b**) with sites
273 affected by mutation highlighted. There were 3 sites of recurrent mutations at
274 residues equivalent to alanine 61 and 65 and lysine 81 of *HIST1H1E*. There were

275 also several additional mutations within the globular domain across variants located
276 between residues 100-110. The globular domain of these genes is a region
277 frequently mutated in other cancers including follicular lymphoma and diffuse large B
278 cell lymphoma.(26, 27) . The observations that the mutations occurred in a
279 conserved region and there were no mutations in one known gene, *HIST1H1A*,
280 supports the hypothesis that these are not passenger mutations and may carry some
281 significance to myeloma pathogenesis.

282 Mutations in *HIST1H1B-E* were tested for their impact on protein function using SIFT
283 analysis. This analysis was possible in 29/31 mutations and 69% (20/29) were found
284 to be damaging (**Supplementary Table 5**). *HIST1H1B-E* mutations did not have a
285 prognostic impact (**Supplementary Figure 3**).

286 CCF analysis showed *HIST1H1E* and *HIST1H1C* mutations to be highly clonal
287 (**Figure 1**) suggesting they are either acquired early in clonal development or
288 selected for at progression to symptomatic disease, but nevertheless play an
289 important role in myeloma pathogenesis in these patients.

290 Mutations were also seen in the core histone proteins 2A (4.5%, 21/463 patients,
291 one frameshift mutation, remainder missense SNVs), 2B (3.7%, 17/463, one
292 frameshift mutation, remainder missense SNVs), 3 (2.8%, 13/463, one frameshift,
293 one nonsense, remainder missense SNVs) and 4 (1.7%, 8/463, all missense SNVs)
294 but with a low frequency of mutation in each family member, with no individual gene
295 being mutated in more than 4 patients. The total number of patients harbouring a
296 mutation in any histone protein (linker or core) was 18% (83/463) with the presence
297 or absence of any mutation having no effect on progression or survival.

298 **Histone modifier mutations: Mutations/deletions in KDM6A/UTX may shorten overall**
299 **survival from diagnosis.**

300 **a) Methylation modifiers**
301

302 Potentially deleterious mutations in histone methyltransferase/demethylase enzymes
303 were found in 24% (112/463) of patients, though the percentage with each gene
304 mutated was low (**Figure 3**). The most frequently mutated gene family in the
305 methyltransferases was *MLL2/3/4/5* (7% of patients, 31/463. By gene: *MLL* 1.7%,
306 8/463, *MLL2* 1.3%, 6/463, *MLL3* 1.5%, 7/463 *MLL4* 1.5%, 7/463 and *MLL5* 1.1%,
307 5/463) but no recurrent mutations were seen across variants. Of 36 mutations
308 (across the 31 patients) 29 were missense SNVs, 4 nonsense SNVs, 2 splice site
309 SNVs and 1 frameshift mutation. As in other diseases mutations in *MLL* family genes
310 are widely distributed across the genes with no conserved sites or regions of
311 mutation (**Supplementary Figure 1**). The majority of mutations identified in our
312 patients were novel but those previously identified in other diseases included one in
313 *MLL3*, p.R190Q (endometrial) (20) and in *MLL4*, p.R297* (large intestine) (28). The
314 presence of *MLL* family mutations in myeloma patients did not have an effect on
315 progression-free or overall survival.

316 No mutations in the H3K27 methyltransferase *EZH2* were detected, in contrast to the
317 finding of recurrent mutations in other B cell malignancies. There were only 2
318 patients with mutations affecting the H3K36 methyltransferase *MMSET*, with none of
319 the *MMSET* activating mutations at p.E1099K (previously identified in MM1.S
320 myeloma cell line)(29) seen. *EHMT2*, the gene encoding the H3K9
321 methyltransferase G9a was mutated in 5/463 patients (1%, all missense mutations)
322 with one in the SET domain (p.Y1097F) and one in the ankyrin repeat 'reader'
323 domain (p.E699K) (**Supplementary Figure 1**).

324 The most frequently mutated demethylase gene was *KDM3B*, 1.5% (7/463) of
325 patients with two splice site mutations, one nonsense mutation and 4 missense
326 mutations, none of which have been previously identified in other cancers in the
327 COSMIC database. The primary site of action of *KDM3B* is H3K9 and deletions of
328 this gene have been implicated in myelodysplastic syndrome associated with 5q-.
329 (30, 31)

330 *KDM6A/UTX* mutations were seen in 1.3% (6/463) of patients, were all missense
331 mutations and were highly clonal (**Figure 1**). p.R118K, had been previously identified
332 in lung cancer (32), p.Q398H in gastric adenocarcinoma (20) whilst another p.G66A
333 occurred at the same residue as the p.G66D mutation previously identified in the
334 OPM-2 myeloma cell line (10). Further analysis of this gene for whole exonic
335 deletions increased the number of patients affected by a potentially inactivating
336 lesion to 3% (15/463). Patients with a *KDM6A* mutation or deletion had a reduced
337 overall survival (OS) compared to wild type on univariate analysis (**Figure 4A**)
338 (medians not reached, logrank p=0.0498, percent alive at 2 years 51% 95%CI (30,
339 85) vs 80% 95%CI (77, 84) with a similar trend for progression-free survival (PFS).

340 **b) Acetylation modifiers**

341

342 The most frequently mutated gene encoding a histone acetyltransferase (HAT) or
343 deacetylase (HDAC) was the HAT *EP300* mutated in 1.3% (6/463) of patients.
344 Mutations in this gene have been previously identified in a number of other
345 malignancies including DLBCL, where they are most commonly found in the HAT
346 enzymatic domain.(33-35) One frameshift deletion (p.S90fs) and one nonsense
347 mutation (p.Q1077*) are likely to result in an absence of functional protein. Of the 4
348 missense mutations one occurs in the active HAT domain (p.P1388S) and so may

349 directly affect the catalytic function of the protein, whilst one in the bromodomain
350 (p.V1079L) and two in the zinc finger binding domain (p.T1775P, p.G1778P) may still
351 have significant effects on the protein function by affecting target binding. Mutations
352 in CREBBP, a closely related member of the KAT3 family of histone
353 acetyltransferases were also found in 3 patients. One mutation, p.R1360Q occurs at
354 the same amino acid as the p.R1360* mutation seen in several diseases including B-
355 NHL (33). EP300/CREBBP have a wide range of targets and are able to acetylate
356 all four histones as well as being involved in many cellular processes linked to
357 cancer such as cell cycle progression, p53 activity, DNA repair and apoptosis.(36)

358 There were no genes encoding histone reader proteins that were mutated in more
359 than 1% (5/463) of patients at diagnosis.

360 **DNA methylation modifier mutations: Mutations in DNA methylation modifiers are**
361 **associated with a shorter overall survival from diagnosis.**
362

363 DNA methylation modifiers were mutated in 4% (17/463) of patients at diagnosis.
364 This included specific mutations previously reported in numerous tumour types such
365 as p.R132C in *IDH1* previously reported in glioma, chondrosarcoma and AML (37-
366 41), and p.R140W in *IDH2* and p.C1378Y and p.Y1661* in *TET2* previously reported
367 in AML/MDS (42-44) and p.E784K in *DNMT3A* previously reported in biliary tract
368 tumours (45). A mutation was also seen at p.E477K in *DNMT3A*, the site of
369 recurrent mutation in AML and MPNs (p.E477* and p.E477fs)(46-48). Collectively,
370 mutations in any DNA methylation modifier (*TET1/2/3* n=11, *IDH1/2* n=2 or
371 *DNMT1/3A/B* n=6) were associated with a shorter OS on univariate analysis, **Figure**
372 **4B** (medians not reached, p=0.045, % alive at 2 years 58% 95%CI (39, 88) vs 80%
373 95%CI (76, 84). There was no significant effect of PFS. This effect on OS with no
374 effect on PFS is explained by a significantly shortened post-progression survival for

375 patients with mutations in DNA methylation modifiers compared to those without
376 (p=0.002, logrank test, data not shown).

377 **Chromatin remodelling complex mutations** 378

379 The most frequently mutated genes involved in chromatin remodelling were *CHD4* in
380 1.9% (9/463, all missense) of patients and *CHD2* in 1.5% (7/463, one frameshift, six
381 missense). Both are members of the nucleosome remodelling and deacetylase
382 complex (NuRD). This highlights the potential role of the NuRD complex in myeloma
383 pathogenesis however its action may not be entirely epigenetic as it has also been
384 recently noted that CHD4 may also have roles in DNA damage repair and cell cycle
385 progression independent of the NuRD complex and epigenetic activity.(49)

386 Other remodelling genes mutated in more than 1% of patients include *ARID1A*
387 (encoding BAF 250a) in 1.3% (6/463, 2 nonsense and 4 missense) and *ARID2*
388 (encoding BAF200) in 1.3% (6/463, 3 nonsense, 1 splice site, 2 missense). Their
389 gene products are part of in the SWI/SNF (sucrose non-fermenting/ switch non-
390 fermenting) remodelling complex and are responsible for its interaction with DNA.
391 Mutations in genes encoding members of this complex have been previously
392 demonstrated to be recurrently mutated in both solid tumours and haematologic
393 malignancies in up to 20% of cancer patients overall.(50, 51) The mechanisms
394 behind this have yet to be fully elucidated and in different diseases has been
395 suggested to be related to the role of the SWI/SNF complex in DNA damage
396 repair,(52) nucleosome positioning, DNase hypersensitivity sites, the regulation of
397 developmental gene expression and/or the interaction of the complex with both
398 histone and DNA modifiers.(53) We found previously identified mutations at p.M918I
399 in *ARID1A* (seen in renal cell carcinoma) (20) at p.Q937* in *ARID2* (seen in biliary

400 tract carcinoma and melanoma) (20, 45), p.Q1611* in ARID2 (seen in squamous cell
401 carcinoma) (54) and p.A1555S in ARID2 (seen recurrently in head and neck
402 carcinoma) (55).

403 **Survival analysis**

404

405 For each class of epigenetic modifier the progression-free and overall survival for
406 those patients with a mutation in any gene within the class were compared to those
407 patients without. In addition those patients with mutations of interest were compared
408 to those without in the following cases, *KDM6A* mutations or deletions, MLL family
409 gene mutations and Histone 1 family gene mutations. An effect on overall survival
410 was found on univariate analysis for *KDM6A* mutations/deletions and DNA modifier
411 mutations as described above. Multivariate analysis using a cox-regression model
412 was therefore carried out considering other factors known to have an adverse effect
413 on overall survival; presence of an adverse translocation t(4;14), t(14;16) or t(14;20),
414 del17p, gain or amplification of 1q, international staging score and age >70. In this
415 model DNA modifier mutations, in addition to del17p, ISS and gain or amplification of
416 1q remained significant but not *KDM6A* mutations/deletions. (**Supplementary Table**
417 **6**).

418 **The frequency of mutations in epigenetic modifiers increases following treatment**

419

420 Longitudinal investigations are planned for the patients in the UK Myeloma XI trial,
421 but at present the majority remain in remission. Therefore, in order to study the likely
422 differences in the frequency of mutations in epigenetic modifiers as disease
423 progresses we utilised available data for a series of 156 previously treated myeloma
424 patients from the University of Arkansas for Medical Sciences (UAMS) who
425 underwent targeted sequencing. Due to the different methods used we restricted our

426 comparison to only those epigenetic modifier genes that have been sequenced in
427 both studies (**Supplementary Table 4**) Results are summarised in **Figure 5A** and
428 **Supplementary Table 7** and show an increase in the number of patients with a
429 mutation in any epigenetic modifier in samples taken at later stages of disease.
430 There is a statistically significant increase in the number of patients with a mutation
431 in any histone methyltransferase gene (6.9%, 32/463 MyXI vs 17%, 26/156 UAMS)
432 or any DNA methylation modifier (1.9%, 9/463 MyXI vs 8.3%, 13/156 UAMS) and a
433 notable increase in histone acetyl-transferase gene mutations (2.4%, 11/463 MyXI vs
434 7.1%, 11/156 UAMS). These changes appear to be the result of increases in
435 mutations in *MLL2*, *MLL3*, *SETD2*, *CREBBP*, *DNMT3A* and *TET2* (**Figure 5B**).

436 The variant allele frequency was compared between the MYXI and UAMS samples
437 (**Supplementary Figure 4**) with no statistically significant differences seen. An
438 analysis of the distribution of mutations across risk groups, as defined by gene
439 expression profile risk score (GEP70) (**Supplementary Figure 5**) and UAMS
440 molecular subgroups (**Supplementary Figure 6**) found a slight overrepresentation of
441 the PR subgroup in those patients with an epigenetic modifier mutation compared to
442 those without.

443 Of note in the UAMS dataset 2 of the 3 mutations in *HIST1H1E* had been previously
444 identified, p.A65P in the MyXI dataset and p.P161S in a lymphoid neoplasm
445 (COSMIC) whilst the third, p.A47V, occurred at the same residue as p.A47P seen in
446 a MyXI patient. This supports the evidence of likely impact of *HIST1H1E* mutations
447 in myeloma suggested by the MyXI analysis. Recurrent mutations were also seen in
448 the UAMS dataset at the same location in *IDH1*, p.R132C and p.R132H, with
449 p.R132C having been also identified in a MyXI patient.

450 Discussion

451

452 We report mutations within genes encoding epigenetic modifiers in myeloma with an
453 impact on pathology and survival at diagnosis and an increased frequency after
454 treatment. The spectrum of mutations in myeloma is broad with no single epigenetic
455 modifier being mutated in a large proportion of patients. Several of the mutations
456 identified have been previously related to cancer pathogenesis and/or may open
457 possibilities for targeted treatment strategies for subgroups of patients. This work
458 changes our understanding of the epigenetic landscape of myeloma exposing a
459 wider spectrum of epigenetic processes than previously recognised, that may be
460 altered in large numbers of patients, affecting disease biology and outcome.

461 One of our key findings is the significant mutation of *HIST1H1E* and similar
462 mutations across Histone 1 family genes in diagnostic samples. Histone H1 acts to
463 control the higher order structure of chromatin by spacing nucleosomes and holding
464 DNA in place as it winds around each nucleosome octamer. It has, therefore, been
465 suggested to affect gene transcription via the modulation of the accessibility of DNA
466 to transcription factors. Mutations in the histone H1 family genes have been found in
467 other haematological malignancies including follicular lymphoma and diffuse large B
468 cell lymphoma.(27, 56) In follicular lymphoma these were also noted to be
469 predominantly in the globular domain and one such mutation (Ser102Phe) was
470 functionally demonstrated to affect impaired ability of histone H1 to associate with
471 chromatin.(56) This is close to several sites of mutation identified in our study
472 between residues 100-110. More recently, histone H1 has also been shown to play
473 a role in regulating DNA methylation via DNMT1 and DNMT3B binding and altering
474 H3K4 methylation by affecting binding of the methyltransferases SET7/9.(26, 57) It

475 might, therefore, be postulated that it is via these mechanisms that mutations in
476 histone H1 may have an oncogenic effect. Analysis of paired sample mutation and
477 DNA methylation analysis will further inform this hypothesis.

478 *HIST1H1E* and *HIST1H1C* mutations (along with *KDM6A* and *ARID2*) were highly
479 clonal, suggesting they may be acquired early in pathogenesis or selected for at
480 progression to symptomatic disease. Our analysis estimates CCF using a method
481 that correlates well with single cell analysis results; however in certain situations
482 copy number alterations or polyclonality may yield anomalous CCF estimates for
483 individual mutations. Future improvements in techniques for calculating CCF may
484 further inform these results.

485 Our analysis identifies 3% of patients at diagnosis with a potentially inactivating
486 lesion in *KDM6A/UTX*. This is lower than the frequency of mutations previously
487 identified (10) and often reported of 6/58, 10%. This previous analysis, however,
488 included cell lines, and when these are removed and only patient samples from the
489 analysis considered the percentage with a lesion falls to 4% (2/49), in keeping with
490 our study.

491 The Myeloma XI study pairs mutation and outcome data giving us the first
492 opportunity to explore any possible association between epigenetic modifier
493 mutations and outcome. Individual epigenetic modifier genes are mutated in small
494 numbers of patients and so the size of our dataset limits the power to detect any
495 specific gene effects. We therefore grouped mutations (11 groups as defined above)
496 and on univariate analysis identified a detrimental effect on overall survival of
497 *KDM6A* mutation/deletion (Log-rank $p=0.0498$) and DNA methylation modifiers (Log-
498 rank $p=0.045$). If a Bonferroni correction for multiple testing were applied to this data

499 the p-values obtained would fall above the level considered significant, however this
500 arbitrary cut off may miss a clinically meaningful effect. Further investigation in future
501 studies will help to clarify this. Notably the effect of DNA methylation modifier
502 mutations on overall survival withstood multivariate analysis and in larger cohorts it
503 would be of interest to investigate the independent association of mutations within
504 this, and other groups, on outcomes. Myeloma is part of a spectrum of malignancies
505 arising from B cell populations at various stages of B cell ontogeny. Mutations in
506 epigenetic modifiers are seen across this spectrum but we can now show that
507 different patterns are seen dependent upon the biology of the population examined.
508 Recurrent mutations in *HIST1H1*, *MLL* and *EZH* gene families have been identified
509 in diffuse large B cell lymphoma and follicular lymphoma.(26, 34) We show that
510 *HIST1H1* and *MLL* mutations are seen in myeloma, although at a much lower
511 frequency, whereas *EZH2* mutations are not seen, suggesting a different pathogenic
512 mechanism. The different spectrum of epigenetic mutations is more marked when
513 we compare lymphoid to myeloid diseases such as acute myeloid leukaemia,
514 myelodysplastic syndromes and myeloproliferative neoplasms, where mutations in
515 DNA modifying enzymes such as *DNMT3A*, *IDH* and *TET2* predominate.(58, 59)
516 We found mutations in these genes in myeloma, but at a much lower frequency.

517 Our results highlight possible targeted treatment approaches for patients either at
518 diagnosis or at relapse. For example patients with a *KDM6A/UTX* mutation or
519 deletion might be amenable to the use of *EZH2* inhibitors, currently in the early
520 stages of clinical development for lymphoma patients. Inhibiting *EZH2*, the H3K27
521 methyltransferase, may counteract the increased H3K27 methylation resulting from
522 inactivation of the demethylase. A recent study also reports that *ARID1A* mutated
523 cancers may be sensitive to *EZH2* inhibition, demonstrating a synthetic lethal effect

524 via the PI3-AKT pathway.(60) Patients with *IDH* mutations might be amenable to IDH
525 inhibitors currently in early stages of development and a more global strategy might
526 be possible for patients with mutations in DNA methylation modifiers with
527 demethylating agents.

528 On comparison with results from focused sequencing of 156 previously treated
529 patients we show an increase in the number of patients with a mutation in genes
530 encoding a histone methyltransferases and DNA methylation modifiers. This
531 suggests that these events may either play a role in disease progression or occur
532 more frequently following exposure to induction chemotherapy in resistant
533 subclones. The change in frequency of mutations in DNA methylation modifiers as
534 myeloma progresses is supported by data showing a change in the methylation
535 pattern at different disease stages.(3) There are several limitations to our
536 comparison, however, including the different sequencing methods and depth. These
537 results will, therefore, need to be validated in matched patient populations following
538 relapse within a clinical trial setting using the same analysis method.

539 This whole-exome analysis of Myeloma XI patients at diagnosis is the first extensive
540 analysis of the spectrum of mutations in epigenetic modifiers in a uniformly treated
541 population in myeloma. An association with clinical outcome for *KDM6A* mutated or
542 deleted patients, and mutations in DNA methylation modifiers is suggested in our
543 dataset but will need validation in larger studies or meta-analysis due to the low
544 overall frequency of the mutations. These data further emphasise the importance of
545 epigenetics in myeloma and provide potential new targets for personalised
546 therapeutic strategies for patients. Our findings support the use of sequencing-
547 based diagnostics in myeloma both at diagnosis and relapse in order to identify
548 potentially prognostic and/or targetable lesions.

550 **Acknowledgements:**

551 We would like to thank all the patients and staff at centres throughout the UK whose
552 participation made this study possible. We are grateful to the NCRI Haemato-oncology
553 subgroup and to all principle investigators for their dedication and commitment to recruiting
554 patients to the study. The principal investigators at the four top recruiting centres were Dr
555 Don Milligan (Heart of England NHS Foundation Trust), Dr Jindriska Lindsay (Kent and
556 Canterbury Hospital), Dr Nigel Russell (Nottingham University Hospital) and Dr Clare
557 Chapman (Leicester Royal Infirmary). The support of the Clinical Trials Research Unit at The
558 University of Leeds was essential to the successful running of the study and the authors
559 would like to thank all the staff including Helen Howard, Corrine Collett, Jacqueline Ouzman
560 and Alex Szubert. We also acknowledge The Institute of Cancer Research Tumour Profiling
561 Unit for their support and technical expertise in this study. Thanks to Tim Vojt for help with
562 figure 3.

563 **Grant support:**

564 This work was supported by a Myeloma UK program grant, Cancer Research UK CTAAC
565 sample collection grants (C2470/A12136 and C2470/A17761), a Cancer Research UK
566 Biomarkers and Imaging Discovery and Development grant (C2470/A14261), and funds from
567 the National Institute of Health Biomedical Research Centre at the Royal Marsden Hospital
568 and Institute of Cancer Research. Work carried out at the Myeloma Institute, University of
569 Arkansas for Medical Sciences was supported by a grant from the NIH. CP is a Wellcome
570 Trust Clinical Research Fellow. FED is a CRUK Senior Cancer Fellow.

571

572

573 Genome data from the Myeloma XI trial patients have been deposited at the European
574 Genome-phenome Archive (EGA, <http://www.ebi.ac.uk/ega/>) which is hosted at the EBI,
575 under accession number EGAS00001001147.

752

753 **Figure Legends**

754

755 **Figure 1**

756 **Cancer Clonal Fraction in genes encoding epigenetic modifiers.**

757 The proportion of tumour cells containing an SNV was calculated in the 370 samples with accurate
758 copy number assessments and plotted as the CCF interval for each sample with the indicated
759 mutation, corrected for coverage. Mutations were considered clonal and shown in red if the upper
760 CCF interval was $\geq 95\%$ and sub-clonal if the upper CCF interval was $<95\%$. The proportion of
761 samples with each gene mutation that were clonal and sub-clonal are shown in the bar chart below the
762 gene name. Epigenetic modifiers were analysed for CCF if they were mutated in $\geq 5/463$ ($>1\%$)
763 patients.

764 **Figure 2**

765 **Site of mutations in the genes encoding histone 1 variants**

766 **A**, The common protein variants are shown with the globular domain of each highlighted in purple.
767 The sites of mutation are indicated by the markers with red dots indicating missense mutations and
768 purple dots frameshift mutations. There was 1 mutation in *HIST1H1B* in 1 patient, 12 mutations in
769 *HIST1H1C* in 12 patients, 3 mutations in *HIST1H1D* in 3 patients and 15 mutations in *HIST1H1E* in
770 13 patients. There were no mutations in *HIST1H1A*.

771 **B**, The common proteins of Histone 1 are aligned and labelled such that 1H1A/H1.1 indicates the
772 protein histone 1.1, encoded by gene *HIST1H1A*, 1H1B/H1.5 indicates the protein histone 1.5
773 encoded by gene *HIST1H1B* etc. The numbers indicate the amino acid number. The protein domains
774 are indicated by the coloured bars overlying the protein sequence, green denotes the N terminal
775 domain, purple the globular domain and red the C terminal domain. Mutations found in the patients
776 sequenced are indicated by coloured square, pink = missense SNV, yellow = frame shift insertion and
777 green = frame shift deletion. At some sites there was more than one patient with a mutation. The
778 overlying arrows indicate amino acids where the mutations in different protein variants occur at the
779 same equivalent amino acid residues.

780 **Figure 3**

781 **Mutations in histone methyltransferases and demethylases.**

782 The methyltransferases and demethylases located at their most commonly recognised site of activity
783 on histone 3 are shown with the percentage of patients harbouring a mutation. Those in bold are
784 mutated in 5 or more patients in the dataset.

785 **Figure 4**

786 **Overall survival is shorter in patients with a *KDM6A* mutation or deletion and those with a 787 mutation in any DNA modifier.**

788 **A**, Kaplan-Meier curves showing patients with a *KDM6A* mutation or deletion (n=15, dashed) and
789 those without (n=448, solid). Progression-free survival median mut/del 16.8 months vs wild type 26.6
790 months (logrank p=0.695). Overall survival medians not reached, (logrank p = 0.0498). Percent alive

791 at 2 years: mut/del 51% 95%CI (30, 85), wild type 80% 95%CI (77, 84). Survival on x-axis is plotted
792 as the time since randomisation.

793 B, Kaplan-Meier curves showing patients with a DNA modifier mutation (n=17: *TET1/2/3* n=11,
794 *IDH1/2* n=2 or *DNMT1/3A/B* n=6, dashed) and those without (n=446, solid). Progression-free
795 survival median mut/del not reached vs wild type 26.6 months (logrank p=0.852). Overall survival
796 medians not reached, (logrank p = 0.0455). Percent alive at 2 years: mut 58% 95%CI (39, 88), wild
797 type 80% 95%CI (76, 84). Survival on x-axis is plotted as the time since randomisation.

798 **Figure 5**

799 **The frequency of mutations in genes encoding epigenetic modifiers at presentation and**
800 **following treatment by class of epigenetic modifier.**

801 **A**, A comparison between the percentage of patients with a mutation in each class of epigenetic
802 modifier at presentation (Myeloma XI data, shown in black bars) and after treatment (UAMS data,
803 shown in gray bars). There is a significant increase in the percentage of previously treated patients
804 with a mutation for those groups indicated by *. (z-test of difference in proportions $P < 0.05$). Those
805 comparisons remaining significant after multiple test correction (Bonferroni method) are indicated by
806 **. Full data is shown in supplementary table 7. Only mutations in genes sequenced in both studies
807 (i.e. the genes sequenced in the UAMS F1 dataset, supplementary table 4) were included for this
808 comparison.

809 **B**, The frequency (%) of mutations in genes of interest within each class

810

Table 1

Epigenetic genes mutated in $\geq 5/463$ ($>1\%$) newly diagnosed patients in Myeloma XI dataset

Gene	No of patients (total = 463)	Percentage
<i>ARID1A</i>	6	1.30%
<i>ARID2</i>	6	1.30%
<i>ARID4A</i>	5	1.08%
<i>ARID5B</i>	5	1.08%
<i>CHD2</i>	7	1.51%
<i>CHD4</i>	9	1.94%
<i>EHMT2</i>	5	1.08%
<i>EP300</i>	6	1.30%
<i>HIST1H1C</i>	12	2.59%
<i>HIST1H1E</i>	13	2.81%
<i>KDM3B</i>	7	1.51%
<i>KDM6A</i>	6	1.30%
<i>MLL</i>	8	1.73%
<i>MLL2</i>	6	1.30%
<i>MLL3</i>	7	1.51%
<i>MLL4</i>	7	1.51%
<i>MLL5</i>	5	1.08%
<i>SETD2</i>	6	1.30%
<i>SETDB1</i>	5	1.08%
<i>TET2</i>	5	1.08%
