43 ABSTRACT

Samples of PM_{2.5} and PM₁₀ have been collected in all of four seasons at seven sites within the city 44 of Jeddah, Saudi Arabia. The samples have been analysed for a range of trace elements. There is a 45 46 large loading of wind-blown dust and the majority of elements are predominantly associated with coarse particles. Enrichment factors, however, show that some elements are markedly enriched 47 48 above crustal abundance. Using mean data for the PM_{2.5} and PM₁₀ fractions from each of the seven 49 sampling sites, health risks have been estimated for particulate matter mass, the elements Cr, Mn, 50 Ni, Pb, As, Cd and V measured in this study, and polycyclic aromatic hydrocarbons using data from an earlier study within Jeddah. Cancer risks are calculated from mean airborne concentrations and 51 52 cancer slope factors for the carcinogenic metals and PAH, but the cancer risks are relatively modest compared to the lifetime risk of mortality due to PM_{2.5} exposure. The risks associated with 53 exposure to V and Mn are considered to be small, while concentrations of cadmium far exceed the 54 European Union Limit Value and World Health Organisation guideline. Cadmium shows a very 55 high crustal enrichment factor but is present predominantly in the coarse particle fraction suggesting 56 57 that local soils and surface dusts are unusually enriched in Cd relative to the global average. Using national data for mortality rates, the excess mortality due to $PM_{2.5}$ exposure has been calculated and 58 amounts to over 1100 deaths annually for the city of Jeddah. 59

60

61 **Keywords:** Particulate matter; PM_{2.5}; PM₁₀; health risk

62 1. INTRODUCTION

Saudi Arabia is a country with a fast growing population enumerated as 30.8 million in 2014. The 63 population is heavily focussed on the major cities and especially Riyadh and Jeddah. The city of 64 65 Jeddah is located on the Red Sea coast of Saudi Arabia and has a population of 3.98 million (in 2014). In addition to its resident population, the sea port and airport of Jeddah act as a gateway for 66 pilgrims entering Saudi Arabia for the traditional Hajj and Umrah in the Holy City of Makkah. 67 68 Jeddah extends considerably further from north to south than from east to west (see Figure 1) with the Red Sea on its western border. However, to the north, south and east of Jeddah lie large areas of 69 70 desert which provides an extensive source for wind-blown dusts.

71

While there have been air quality studies in the inland city of Makkah (Al-Jeelani, 2009; Simpson et 72 al., 2014), and the coastal town of Yanbu to the north of Jeddah (Khalil et al., 2016), these have 73 focussed largely on gas phase pollutants and only the latter study provides limited data for 74 particulate matter concentrations. Mean concentrations of PM_{10} and $PM_{2.5}$ in Yanbu based on six 75 years of observations are reported as 70 μ g m⁻³ and 60 μ g m⁻³ respectively (Khalil et al., 2016). The 76 small differential between PM_{2.5} and PM₁₀ measured between 2000 and 2005 in Yanbu is rather 77 surprising and diverges from the experience of many other sites in western Saudi Arabia (e.g. 78 79 Khodeir et al., 2012).

80

There have been a number of studies within and close to the city of Jeddah. Kadi (2014) reports measurements of total suspended particulate matter (TSP) collected with high volume samplers together with analyses of Al, Ba, Ca, Cu, Mg, Fe, Mn, Zn, Ti, V, Cr, Co, Ni, As and Sr. These were made at seven sites within Jeddah, and concentrations of the various metallic components and crustal enrichment factors are reported. Enrichment factors of elements at the more polluted sites range approximately from 10-60 whilst for Cu and Zn, these are much higher at some of the sites with a peak value of over 700 for Cu at a site influenced by light industry and road transport

activities. The data show very large inter-site differences for the majority of the elements analysed.
In another paper, the same author (Kadi, 2009) also determined soil composition and reports a
strong elevation in lead and zinc content at heavily trafficked sites.

91

Khodeir et al. (2012) report data from seven sampling sites within Jeddah from samples collected in 92 2011. They report overall mean mass concentrations of $28.4 \pm 25.4 \ \mu g \ m^{-3}$ for PM_{2.5} and $87.3 \pm$ 93 $47.3 \ \mu g \ m^{-3}$ for PM₁₀ with considerable spatial and temporal variability. The average ratio of PM_{2.5} 94 to PM_{10} of 0.33 appears typical of data from western Saudi Arabia but is very different from the 95 pattern of behaviour reported above from Yanbu. Khodeir et al. (2012) provide a factor analysis 96 97 model with Varimax orthogonal rotation to determine the sources contributing to concentrations of 98 PM_{2.5} and PM₁₀. These include heavy oil combustion, resuspended soil and a mixed industrial 99 source for both PM_{2.5} and PM₁₀, and for PM_{2.5} road traffic and a second industrial source, and for PM₁₀, marine aerosol. The main contributor to PM_{2.5} was identified as heavy oil combustion while 100 101 for PM₁₀ it was wind-blown soil. Crustal enrichment factors relative to Fe in PM_{2.5} were very high for S (average 3000), Se (14000) and Cd (8800). The same elements were enriched in PM_{10} , with 102 Se (2400) and Cd (15000) showing the highest enrichment. 103

104

105 Alghamdi et al. (2015a) sampled PM₁₀, PM_{2.5} and PM₁ fractions and measured the elemental 106 composition of PM_{2.5} in Jeddah during March 2012. The data were disaggregated into dust storm 107 and non-dust storm periods. Based upon enrichment factors, it was concluded that in both non-dust storm and dust storm periods, the main sources of Na, Mg, Si, K, Ca, Ti, Cr, Mn, Fe, Rb and Sr are 108 109 of a crustal type whereas S, Cl, Co, Cu, Zn, Ga, As, Pb and Cd as well as V and Ni are predominantly anthropogenic. The conditions giving rise to dust storms were also considered. 110 Crustal enrichment factors relative to aluminium in PM_{2.5} were highest for S (average 2792), As 111 112 (2581), Cd (28,699) and Pb (5879). Enrichment factors were highest during non-dust storm conditions but the same elements also showed enrichment during dust storm conditions. From 113

samples collected in Riyadh, Alharbi et al. (2015) found that concentrations were considerably
higher in summer than winter which was attributed to dust storm activity. Crustal species such as
Fe, Mn, Ti, Ca and Mg were found at appreciably higher concentrations in summer.

117

Porter et al. (2014) analysed PM₁₀ data collected in 2010-2011 in sites in and around Jeddah and at 118 119 a remote background site for comparison. Data were collected with automated beta gauges making 120 diurnal variations in concentrations available. The PM₁₀ concentrations do not show a very consistent seasonal pattern with major differences between the various sites. PM₁₀ showed a 121 reduced concentration at weekends relative to weekday concentrations clearly indicating an 122 anthropogenic influence. Data from Yanbu (Khalil et al., 2016) showed marked diurnal variations 123 that do not link clearly with road traffic activity and appear more likely to be influenced by the 124 speed of local winds. 125

126

127 Shaltout et al. (2013, 2015) have reported concentrations of $PM_{2.5}$ and trace elements in the city of 128 Taif in western Saudi Arabia. In the more recent study (Shaltout et al., 2015) they report $PM_{2.5}$ 129 concentrations of 50, 57 and 37 µg m⁻³ respectively at traffic, industrial and residential sites.

130

Measurements of particulate matter made at a rural background site (Hada Al-Sham) about 60 km 131 east of the Red Sea coast and the city of Jeddah are reported by Lihavainen et al. (2016). Mean 132 PM_{10} concentrations were $109 \pm 89 \ \mu g \ m^{-3}$ and $PM_{2.5}$, $38 \pm 68 \ \mu g \ m^{-3}$ hence showing a clear 133 134 dominance of coarse mode particles. PM₁₀ concentrations were markedly higher in January to June than in July to December, but given the limited duration of sampling, it is difficult to attach any 135 significance to this. The mass fraction of $PM_{2.5}$ was around 0.35 and showed maxima in February 136 and December with minimum concentrations in March, June and July. PM₁₀ and PM_{2.5} showed 137 138 diurnal variations which appeared to be related to traffic activity with reduced concentrations at the weekend. The strength of the diurnal variation, apparently connected with traffic, is rather 139

surprising given that it was a rural site. However, the authors speculate that the strong sea breeze
circulation with diurnal changes in wind direction and speed may have been an important influence.
The fact that black carbon showed a very different diurnal pattern peaking at night suggests that
road traffic was probably not the cause.

144

Two studies have reported concentrations of particulate and vapour phase polycyclic aromatic hydrocarbons (PAH) sampled at sites within and north of Jeddah (Alghamdi et al., 2015; Harrison et al., 2016). Alghamdi et al. (2015) carried out a source apportionment study reporting that the major identifiable sources of PAH were gasoline vehicles (17%), industrial sources, particularly the oil refinery (33%) and diesel/fuel oil combustion (50%).

150

151 **2. EXPERIMENTAL**

Full details of the sampling sites and analytical methods are given by Khodeir et al. (2012). In the 152 interests of completeness, brief details are provided here. The sampling sites and brief details of 153 their characteristics are provided in Table 1, while Figure 1 shows their location within the city of 154 Jeddah and in relation to major local sources. In particular, the desalination plant is notable as it 155 burns heavy fuel oil and emits through two elevated chimneys. The older parts of Jeddah lie to the 156 south, where there is a concentration of light and heavy industries, mainly concentrated around the 157 port and refinery area (see Figure 1). In contrast, the north of Jeddah is more recently developed, 158 with less industry and lower population density. Hussein et al. (2014) provide a valuable map 159 which shows the distribution of light and heavy industries and major facilities in the city. 160

161

PM_{2.5} and PM₁₀ were sampled using an automated cartridge collector unit (ACCU) sampler in the
period June 2011 to June 2012. Daily samples of 24 hours duration were collected on alternate days
on 37 mm, 0.2 μm pore size Gelman Teflo filters. Chemical analysis was by energy dispersive x-

ray fluorescence after filter mass had been determined on a micro-balance (Mettler-Toledo ModelMT5).

167

Samples were collected through all seasons of the year, the number at each site appearing in Table2.

- 170
- 171

3. **RESULTS AND DISCUSSION**

172 The sampling sites used in this study were the same as those used by Khodeir et al. (2012) for their receptor modelling work, but the study now reported differs in important ways from the work of 173 174 Khodeir et al. (2012). Firstly, a substantially larger number of samples was collected, and at all sites, samples were collected in all of the four seasons of the year. This was in order to estimate 175 annually-averaged exposure, rather than that in just one season of the year. The seasonal variations 176 have not been analysed as they are not directly relevant to the topic of this paper, which focusses on 177 the consequences of long-term exposure. Secondly, Khodeir et al. (2012) pooled their data and did 178 179 not look at it on an individual site basis. We now look at site-specific information for PM mass and selected health-relevant trace constituents. 180

181

A large number of elements was analysed and the data are summarised for individual sites in 182 relation to means and standard deviations in Tables S1 to S7 in the Supplementary Information. As 183 this study is focussed upon the health risk associated with particulate matter exposures within the 184 city of Jeddah, the data analysis has focussed upon $PM_{2.5}$ and PM_{10} mass and a number of specific 185 chemical constituents for which there are significant health concerns, and for which regulatory 186 187 guidelines and standards are available. Those elements are chromium (Cr), nickel (Ni) and arsenic (As), which are of concern because of their carcinogenicity, lead (Pb) which is a potent neurotoxin, 188 manganese (Mn) which can affect neuro-behavioural function, vanadium (V), which is a potent 189 respiratory irritant, and cadmium (Cd) which leads to an increased risk of renal dysfunction. 190

191 Regulatory standards and guidelines relating to chronic exposure to these constituents and to $PM_{2.5}$ 192 and PM_{10} mass appear in Table 3. This contains both concentration guidelines (listed as a 193 concentration) and cancer slope factors (presented as incremental lifetime risk per unit of 194 concentration). In the case of chromium, Cr(VI) is a potent respiratory carcinogen, while Cr(III) is 195 relatively benign, hence the cancer slope factors and concentration guideline relate only to the 196 former oxidation state.

197

Mean concentrations of the health-related particle size fraction masses and chemical species at the 198 seven sampling sites and the overall mean of all sites appear in Table 4. There has been no attempt 199 200 to elucidate seasonal patterns because of the limited number of samples collected in each season at 201 each of the sites (see Table 2). It is clear from Table 4 that PM_{10} mass far exceeds $PM_{2.5}$ mass at all of the sites and that this is also the case for many of the elemental constituents. The split between 202 fine particles (PM_{2.5}) and coarse particles (PM_{2.5-10}) is shown for all constituents in Figure S1 and 203 for the elements of health concern, in Figure 2. It may be seen from Figure S1 that the typical 204 205 crustal elements, Ca, Ti, Fe, Si and Al are 90% or more in the coarse fraction consistent with a large input of crustal dust to the samples as has been observed in earlier studies (Rushdi et al., 2013; 206 Hussein et al., 2014). Those elements of health concern which show a larger contribution from the 207 208 fine fraction indicative of anthropogenic sources are Ni, As, V and Pb, for which 40-60% lies in the fine fraction. The question of anthropogenic contribution to concentrations has been further 209 examined through the calculation of crustal enrichment factors according to the method described 210 by Pant et al. (2015) and Table 5 shows averaged crustal enrichment factors for the elements of 211 concern calculated separately for the PM₁₀ and PM_{2.5} size fractions. If the enrichment factor of 5 is 212 213 taken as the threshold for a significant enrichment above crustal ratios, then in the PM₁₀ fraction, V shows a slight enrichment, with As appreciably enriched, and Pb and Cd showing very large 214 enrichments. In the PM_{2.5} fraction, Ni now shows significant enrichment with a larger enrichment 215 216 of V and substantial enrichments of As, Pb and Cd.

Referring to Table 4, site 2 has the highest concentration of PM_{10} , but the second lowest of $PM_{2.5}$, 217 suggesting a local source of coarse dust, possibly resuspension from the dense traffic at this site. 218 Site 3 is located in a predominantly residential area, with substantial light industry locally, and a 219 220 visit to the site revealed recent tyre and waste oil burning. There is a marked contrast to site 1, also in a residential area, but without intense vehicle traffic. Site 1 shows markedly lower 221 222 concentrations of both PM₁₀ and PM_{2.5} mass than the other sites as well as appreciably lower concentrations of many of the trace elements, especially Pb and As. The site showing the highest 223 concentrations of Ni and V is site 6 which is located most closely to the oil refinery and the port and 224 shipyard, although with the prevailing winds coming predominantly from the NNW, it is unlikely to 225 226 have a high exposure to emissions, especially from the oil refinery. Nonetheless, the elevated concentrations of these elements are indicative of a fuel oil combustion source influencing this site. 227 Some evidence of this is also seen in elevated concentrations at site 5 which is also in the area of 228 Jeddah closest to the oil refinery and port. Concentrations of Pb and As are elevated at all sites 229 except for rather lower concentrations at site 1 which is in a residential area in the north of Jeddah 230 231 and remote from major industrial activity. The highest concentrations of Pb in both the PM₁₀ and PM_{2.5} size fraction appear at sites 3 and 4, and since leaded additives are not used in gasoline in 232 Saudi Arabia, must result from one or more local industrial sources. 233

234

Hussein et al. (2014) measured particle mass and number (D_p 0.25-32 µm) through the year 2012 at 235 a sampling site on the campus of King Abdulaziz University in Jeddah. The diurnal variation of 236 both PM₁₀ and PM_{2.5} on workdays showed a pattern typical of an influence of traffic emissions. 237 The concentration of total particle number, but not of PM_{2.5} or PM₁₀ mass showed a marked 238 239 elevation in a wind sector centred on 250°, leading Hussein et al. (2014) to infer that the industrial city in the south of Jeddah is the main source of particulate matter. They also report that the PM_{10} 240 concentration shows a clear U-shaped dependence upon wind speed, which is characteristic of a 241 contribution of wind-blown dust at high wind speeds, with dilution of emissions below the 242

threshold for dust resuspension (Harrison et al., 2001). The occurrence of dust storm events in

Saudi Arabia is well documented (Alharbi et al., 2013; Kutiel and Furman, 2003).

245

246 Aburas et al. (2011) measured lead concentrations in the air of Jeddah in 2008-9, seven years after the phase-out of leaded gasoline in Saudi Arabia. The mean lead content of PM_{25} was 73 ng m⁻³ 247 (range 4-446 ng m⁻³), with crustal enrichment factors (relative to K) at four sites of 761 to 15080. 248 Concentrations were markedly higher at two sites in the south of Jeddah (King Abdulaziz 249 250 University campus and Alfayhaa district) which was attributed to very high traffic density and the proximity to the industrial zone. Rushdi et al. (2013) report concentrations and enrichment factors 251 252 (relative to Al) for Na, Mg, Al, Si, P, S, K, Ca, Mn, Fe Ni, Cu, Zn and Ba. The mean enrichment factor for Ni was 16.3. The only other analyte showing an elevated enrichment factor was S, 253 suggesting fuel oil combustion as the source. Measurements from Taif in western Saudi Arabia 254 made on samples collected in 2011-12 showed average concentrations of Mn of 34-52 ng m⁻³; Ni of 255 3.5-4.0 ng m⁻³; and Pb of 6.3-8.5 ng m⁻³ across traffic, industrial and residential sites. These are in 256 all cases lower than those measured in our study and suggest that Jeddah is subject to greater levels 257 of pollutant emissions. 258

259

260 The results for Cd are quite surprising. This shows substantial enrichment relative to crustal abundance in both the PM₁₀ and PM_{2.5} size fractions (Table 4) and the predominant presence in 261 coarse particles (see Figure 1) seems to suggest either that the local soils have an abnormal 262 geochemical enrichment of Cd or that there is a widespread source of coarse Cd arising from an 263 industrial process. However, such a process would need to be widespread in order to cause such an 264 extensive enrichment across all of the sites. It is notable that Alharbi et al. (2015) measured 265 concentrations of Cd in PM₁₀ in Riyadh of ca. 180 ng m⁻³ during dust storm periods which exceeded 266 the non-dust storm concentrations by a factor of 2.3-fold. Such concentrations are broadly 267 consistent with those in our measurements from Jeddah which strongly suggests an abnormal 268

enrichment of cadmium in surface soils in Saudi Arabia. Alghamdi et al. (2015a) also report very
high enrichment factors for Cd in PM_{2.5} sampled in western Saudi Arabia with average
concentrations in this size fraction in excess of 10 ng m⁻³, and appreciably higher on dust storm than
non-dust storm days. Unfortunately, Cd concentrations were not reported by Kadi (2014) and Cd
was not included in the factor analysis conducted by Khodeir et al. (2012), and consequently that
work does not shed light on the likely sources of Cd.

275

276 **3.1** Health Risk Assessment

Comparing the mean concentrations in Table 4 with the standards and reference concentrations in 277 278 Table 3, it is clear that concentrations of V are not a matter of concern. However, concentrations of Cd, even those in the PM_{2.5} fraction, exceed the recommendation of WHO (2000) and the EU Limit 279 Value of 5 ng m⁻³. The likely health consequences of such an exceedence are very hard to estimate 280 particularly as there are no quantitative exposure-response functions relating airborne 281 concentrations of Cd to the progression of kidney disease. There seems to be ample evidence for 282 high concentrations of Cd in the atmosphere of Saudi Arabia and this warrants further study in 283 relation to potential risks for human health. Concentrations of PM₁₀ far exceed the WHO and EU 284 requirements for this size fraction, and those for PM_{2.5} exceed the WHO (2006) recommendation at 285 all sites and exceed the EU recommendation of 25 μ g m⁻³ at site 3, but not the other sampling sites. 286 287

In Table 6, health risks associated with the mean exposures have been calculated for those pollutants for which there are quantitative exposure-response functions available. In addition to the pollutants in Table 4, polycyclic aromatic hydrocarbons have been included using the cancer slope factor recommended by WHO (2000) and a mean concentration from three sites within Jeddah reported by Alghamdi et al. (2015b). The concentration used is for benzo(a)pyrene, which following the guidance of WHO (2000), is taken as a marker compound for the PAH mixture. As recommended by WHO the unit risk has been applied to the concentration of this compound, but

the risk estimation applies to the entire PAH mixture. Considering the chemical carcinogens, the highest risk appears to apply to Cr, but the value is an upper limit which assumes that all of the Cr exposure is in the form of Cr(VI) which is very improbable. This therefore represents an upper limit to the risk associated with Cr exposure. The risk is quite high and studies of the oxidation state of Cr in local airborne dusts would be well justified. Risks associated with exposure to As and PAH are of somewhat lesser magnitude but still exceed those calculated for Ni exposure.

301

302 In the case of PM_{2.5}, a coefficient for all cause mortality has been taken from WHO (2006), and rather than the usual mortality burden calculation, an incremental risk has been estimated for the 303 304 mean concentration exposure assuming a mean life expectancy of 74.5 years. This reveals a risk associated with PM_{2.5} exposure which substantially exceeds the risks associated with the chemical 305 carcinogens, which is logical as the $PM_{2.5}$ exposure includes exposure to the associated chemical 306 carcinogens which present a subset of the mortality risks associated with PM_{2.5} exposure. The work 307 of Pope et al. (2002) and Lepeule et al. (2012) has shown a significant association between $PM_{2.5}$ 308 309 exposure and lung cancer mortality in the ACS cohort, but the lung cancer risk is only a component of the overall all cause mortality risk. Harrison et al. (2004) considered whether exposure to the 310 chemical carcinogens within PM_{2.5} could explain the carcinogenicity demonstrated by Pope et al. 311 312 (2002). Their conclusion was that it was quite plausible that the chemical carcinogens present could explain the observed carcinogenicity, which serves to confirm the view that the risk associated with 313 exposure to the specific chemical carcinogens is only one part of the overall risk to health from 314 PM_{2.5} exposure which has been associated with a range of cardiopulmonary diseases. The mean 315 concentration of Ni in the Jeddah samples falls significantly below the EU and EPAQS 316 recommendation of 20 ng m⁻³ serving to confirm that the cancer risks associated with Ni exposure 317 are not excessively high. However, the recommendations of the EU and EPAQS for As of 6 ng m⁻³ 318 and 3 ng m⁻³ respectively are appreciably exceeded in Jeddah and there is a good case for further 319 investigating the source of emission of this element and seeking to take action to mitigate the risk. 320

The USEPA IRIS reference concentration of 50 ng m^{-3} for manganese is a highly precautionary 321 value designed to protect against impairment of neuro-behavioural function. It is exceeded by a 322 factor of up to almost four-fold at the Jeddah sampling sites, but this factor is relatively small 323 324 compared to the large in-built margin of safety and it seems unlikely that manganese presents an important risk to public health. The crustal enrichment factors in Table 5 show little evidence for 325 anthropogenic emissions and hence the majority of exposure is from crustally-derived material in 326 327 which the manganese may be significantly less bio-accessible than in the industrial exposures used as the basis for setting the reference concentration. In the case of lead, the exposure concentrations 328 in PM₁₀ at many of the sites exceed the USEPA (1996) and EPAQS (1998) recommendations. Air 329 330 quality standards for lead are designed to protect the developing infant from neuro-developmental effects which have been shown to lead to a reduction in IQ. The fact that the concentrations in 331 Jeddah exceed the regulatory guidelines from these jurisdictions is a matter of some concern. The 332 lead concentrations reported by Aburas et al. (2011) are considerably exceeded by the recent 333 measurements suggesting that there is a significant industrial source or sources in the south of 334 335 Jeddah which is responsible for the substantial elevation of concentrations at sites in this part of the city. It is notable that lead concentrations at the most northerly site (site 1) are very much lower and 336 within the acceptable range. 337

338

Wery few studies have provided data on the effects of mixtures of pollutants, and it is not possible to comment on the possible interactions. It can reasonably be expected that the effects of the chemical carcinogens are additive, but as noted above this effect is included in the overall toxic effect of PM_{2.5} as an exposure metric.

343

344 **3.1.1** *Premature mortality due to PM*_{2.5} *exposure*

The latest demographic information available for Jeddah relates to the year 2014. It listspopulations for 60 areas of the city, which have been classified according to their similarity to the

areas represented by the sampling sites in Figure 1 and Table 1. The land use types are shown
diagrammatically in Figure 3, and are listed in Table S8, both of which include population data.
Table 7 shows a calculation of premature mortality according to the different district types for
Jeddah, using both the 2014 population data for the districts listed in Table S8, as well as the total
Jeddah population, including districts beyond the boundaries shown in Figure 3, making the
questionable assumption that growth in the population is distributed in the same way as the 2014
population within Table S8.

354

In the approach used to estimate the burden of premature mortality, the burden is linearly related to 355 356 both the exposure concentration and the population exposed. Thus for a similar concentration of PM_{2.5}, the overall number of premature deaths will be greater in a larger city, while in a city of 357 similar size to Jeddah, the burden will be greater if the mean PM_{2.5} concentration is higher. The 358 World Health Organization has recently reviewed air quality data from around the world (WHO, 359 2016). While measured data for PM_{10} are plentiful, measurements of $PM_{2.5}$ are far less abundant, 360 and in many cases have been crudely estimated from the PM_{10} data. Measured concentrations vary 361 greatly between countries. Australia reports some of the lowest PM_{2.5} concentrations, with annual 362 means ranging from 5-10 μ g m⁻³. European concentrations are typically a little higher with annual 363 means mostly in the range of 10-20 μ g m⁻³ in western Europe and 20-40 μ g m⁻³ in eastern Europe. 364 Concentrations in China and India are typically higher, with most in the range of $30-100 \ \mu g \ m^{-3}$ and 365 some exceeding 100 μ g m⁻³. The mean of 10 sites in Delhi in 2013 was 122 μ g m⁻³. The WHO 366 data for PM_{2.5} concentrations in Saudi Arabia are all estimated from PM₁₀ measurements and range 367 from 65 to 156 μ g m⁻³ in 2014. These include a mean for Jeddah of 68 μ g m⁻³. This concentration 368 well exceeds those reported for Jeddah in Table 4, but this may be due, at least in part, to the 369 calculation method of WHO as opposed to direct measurement. This wide range of PM_{2.5} data 370 implies that many countries will have considerably lower mortality rates per million of population 371

due to $PM_{2.5}$ exposure than calculated in this work for Jeddah, while in others the rates will be higher.

374

A further factor to be considered is that almost all buildings and cars in Jeddah are air conditioned. Janssen et al. (2002) have shown that in the United States there appear to be lower rates of some diseases associated with PM_{10} exposure in areas with a high percentage of homes with air conditioning, as this can reduce exposures. This implies that the estimated premature mortality shown in Table 7 may be an over-estimate, but this effect has not to date been established for $PM_{2.5}$ exposure.

381

382 **4. CONCLUSIONS**

It is clear from the high concentrations of the crustally-related elements such as Ca, Fe and Si that 383 crustal material in the form of wind-blown soil and dust makes up a substantial proportion of 384 particulate matter in Jeddah. It is predominantly in the coarse $(PM_{2.5-10})$ size fraction, but a 385 386 significant proportion lies also in the fine fraction. Of the health-related elements, only Ni, Pb, As, Cd and V show significant anthropogenic enrichment which is most marked in the fine particle 387 fraction, except for Cd. Comparison with health-related guidelines suggest that the risks associated 388 389 with exposure to Mn and V are very modest or wholly negligible, while the chemical carcinogens Ni, Cr and As present a smaller risk from chronic exposure than does exposure to PM_{2.5}. This is 390 unsurprising as PM_{2.5} exposure has been shown to be associated with a range of cardiopulmonary 391 diseases, including lung cancer which is only a sub-component of the overall health impact of PM_{2.5} 392 exposure. Inclusion of data for PAH from an earlier study shows that these also do not represent a 393 394 large risk in relation to the overall risk of PM_{2.5} exposure. The largest potential risk from the chemical carcinogens relates to Cr, but the calculated risk is an upper limit which makes the 395 pessimistic and probably unrealistic assumption that all of the Cr is present in the Cr(VI) oxidation 396 397 state. Were this oxidation state to make up only a small proportion of the Cr content, then the

estimated risk would be greatly reduced. The enrichment factor for Cr is very small indicating that 398 most Cr arises from the local soils and dusts and could not readily be abated. One unexpected 399 finding is the very high enrichment factor for Cd. The concentrations measured in this study are not 400 401 dissimilar from those reported in earlier studies from both Jeddah and Riyadh, and the fact that the 402 enrichment is broadly similar in both the fine and coarse particle fractions suggests that there is an abnormal geochemical abundance of Cd in local surface soils which could be readily verified by 403 404 chemical analysis. The calculated Cd exposures exceed health-based guidelines by a small factor in 405 the PM_{2.5} size fraction and a much larger factor in PM₁₀. However, if the Cd is associated with surface soils, it seems likely that its bio-accessibility is limited and hence the risk to health may be 406 407 relatively modest.

408

The health risk associated with chronic exposure to $PM_{2.5}$ has been estimated in the form of premature mortality. This shows that total deaths influenced by chronic exposure to $PM_{2.5}$ exceed 1100 for the 2014 population of Jeddah, making this a very significant public health problem.
