## Abstract

In earthquake prone areas, wind and earthquake loads are assumed to be statistically uncorrelated, therefore their interaction is ignored by existing design guidelines. However, the fact that strong earthquake events are commonly followed by aftershocks and that wind is constantly flowing at high speeds around wind farms increase the probability of their joint occurrence, thus making current design assumptions questionable. This investigation shows that multi-hazard scenarios magnify strength demands of wind turbine towers designed against isolated load conditions, hence modifying their performance level. It is also shown that, under certain conditions, the probabilities associated to the joint occurrence of earthquake and low to strong wind events match or exceed those related to the original design, thus rendering wind energy infrastructure susceptible to unforeseen damage.

**Key words:** Earthquake; Wind; Load Interaction; Multi-hazard; Performance level; Wind turbine tower

## Notation

$A$	Area exposed to wind	$\Gamma$	Characteristic structural density
$C_D$	Drag coefficient	$\beta$	Modal exponential
$C_{prob}$	Probability factor	$\Upsilon$	Generalised quantity
$D$	Section diameter	$\varphi$	Modal shape
$F$	Force	$\mu$	Ductility factor
$H$	Height of building	$\rho$	Air density
$I_u$	Turbulent intensity	$\sigma$	Standard deviation of wind velocity
$M_s$	Magnitude scale	$\omega$	Natural frequency
$N$	Number of earthquake events	$\xi$	Structural damping
$P_J$	Probability associated to load J		
$PGA$	Peak ground acceleration		
$R_\mu$	Strength reduction factor		
$\bar{U}$	Average wind velocity		
$V_{s30}$	Upper 30-m mean shear wave velocity		
$a, b$	Site-dependent parameters		
$d$	Structural displacement		
$m$	Structural mass		
$n_0$	Fundamental frequency of vibration		
$p$	Load		
$s$	Load gradient		
$t$	Section thickness		
$u_y$	Yield displacement		
$z$	Vertical coordinate		

## 1. Introduction

In the past decades, regions across the world have been identified where the energy production of Class I and Class II wind energy increases exponentially. This is largely due to the availability of

1 natural resources, technological developments and qualified labour. The fast growing of energy  
2 generation however requires careful consideration of the type of infrastructure that can fulfil the  
3 demands in terms of strength, resilience and innovation. In earthquake-prone regions, tectonic and  
4 environmental conditions make infrastructure often susceptible to earthquakes and wind effects  
5 both during construction and once in operation. Notwithstanding that, current engineering practice  
6 disregards their simultaneous occurrence even though past earthquake records show that further  
7 ground accelerations can occur within days or even hours from main events. Examples of this include  
8 the earthquake that hit the Sichuan Province in China in 2008 ( $M_s = 7.9$ ) which was followed by 12  
9 weeks with 42 aftershocks ranging in magnitude between  $5 < M_s < 6.4$ , killing over 87,000 and  
10 leaving over £56bn in losses (Daniell et al., 2012). The earthquake that hit Nepal in 2015 ( $M_s = 7.8$ )  
11 killing more than 8,000 (Amos, 2015) was followed by 30 aftershocks of  $M_s < 5$  occurring within  
12 three weeks and killing 200 more. More recently, the earthquakes that hit Ecuador in 2016 ( $M_s =$   
13  $7.8$ ) killing over 600, were followed by over 55 aftershocks in the first 24 hours (Shankar, 2016).  
14  
15  
16  
17

18 Past research has contributed to better understand the mechanisms through which extreme load  
19 events affect infrastructure. Martinez-Vazquez (2017) showed that the combination of earthquakes  
20 and wind would decrease the value of strength reduction factors that are calculated by ignoring the  
21 impact of wind during earthquake. Kiyomiya et al. (2002) suggested that wind turbines have  
22 adequate earthquake resistance provided these are designed against typhoons, which could be the  
23 case of offshore wind turbines but is not shared practice for onshore infrastructure design.  
24 Furthermore, Diaz and Suarez (2014) demonstrated that operational earthquake combined with  
25 design wind load tend to over-stress the tower section hence increasing the strength demand  
26 established under isolated wind conditions. The present paper thus aims at enhancing our  
27 understanding of multi-hazard load conditions and their effect on wind energy infrastructure.  
28  
29  
30  
31  
32

33 The paper is organised as follows, section 2 describes the assembling process of two databases, one  
34 containing historical earthquake records and the other containing synthetic wind fields. Section 3  
35 focuses on the estimation of generalised forces acting on three wind turbine towers and the  
36 calculation of their dynamic response. The associated probabilities are discussed in section 4 whilst  
37 the estimation of strength and ductility demands related to multi-hazard scenarios is presented in  
38 section 5. Some final remarks are provided in section 6.  
39

## 42 **2. Earthquake and wind record database**

43 Earthquake records of magnitude  $5.3 \leq M_s \leq 7.36$  recorded on alluvium and with distances from  
44 geological faults of up to 57 km were downloaded from the PEER (2016) ground motion database.  
45 These records are assumed to be representative of alluvium and firm soils once it has been shown in  
46 Miranda (1993) that without much variation they would produce similar strength demands to  
47 structures located on either soil type. These records have a duration which oscillates between 30  
48 and 80 s and were measured at a time interval of 0.1 s. The list of historic earthquake records is  
49 provided in Table 1 which also shows the associated epicentral distance, shear wave velocity ( $v_{s30}$ ),  
50 and peak ground acceleration (PGA).  
51  
52  
53  
54  
55

56 **TABLE 1**

57  
58 On the other hand, a wind record database was established based on the simulation procedure  
59 reported in Martinez-Vazquez and Rodriguez-Cuevas (2007) which follows the conditional simulation  
60  
61  
62  
63  
64  
65

proposed by Vanmarcke et al. (1993). The simulation algorithm requires knowledge of recorded data in at least two points within the region of interest and enables inferring properly correlated wind data series at intermediate points. The two initial data series were calculated by using classical Monte Carlo techniques whereas intermediate points were calculated at 11 stations covering 250 m along a vertical axis. The mean velocity  $\bar{U}$  and turbulence intensity  $I$  - defined as the ratio between the standard deviation and the mean ( $\sigma/\bar{U}$ ) - are shown for each simulation point in Table 2 for the case in which  $\bar{U} = 20 \text{ ms}^{-1}$ . This table also shows how simulated ( $s$ ) and theoretical ( $t$ ) values compare.

TABLE 2

According to the data in Table 2, the average ratio  $\bar{U}_t/\bar{U}_s$  is of 1.028 whereas the mean square error associated to the simulated turbulence intensity is of 0.002. The theoretical wind velocity and turbulence intensity were determined based on a standard exponential law i.e.  $U_z = (z/z_{ref})^\alpha$  using  $\alpha = 0.22$  and  $I_{u,10} = 0.295$  which correspond to suburbs. Table 3 shows the target and calculated cross-correlation in the lower and upper triangular matrices respectively, where Point 1 corresponds to that located at  $z = 10 \text{ m}$ . It can be seen in the table that the accuracy of the simulation increases with the proximity between points – see for example the values around the main diagonal. The overall mean square error across cross-correlation results is of 0.0073 which was considered acceptable for this investigation.

TABLE 3

### 3. Generalised forces acting on wind turbines and related dynamic effects

Three wind turbine towers of 150 m, 200 m and 250 m height were identified. These are assumed to be made of steel with specific weight of  $7850 \text{ kgm}^{-3}$ , Young's modulus of  $200 \times 10^9 \text{ Nm}^{-2}$ , damping level of 5%, and having variable section across their length whilst fixed at their base. The geometry and natural vibration frequency of each tower are shown in Table 4.

TABLE 4

Earthquake forces ( $F_{EQ}$ ) are proportional to the mass of the structure whilst wind forces ( $F_W$ ) were derived from Bernoulli's principle:  $F_W = 1/2 \rho C_D A \bar{U}^2$  – where  $\rho$  is the density of the air,  $C_D$  is a drag coefficient (taken as 1.4), and  $A$  is the projected area of the segment exposed to wind. Generalised forces,  $F_{EQ}^*$  and  $F_W^*$ , were calculated by using Eq. (1), where  $\Upsilon(z)$  represents force or structural mass per unit length,  $z$  is a vertical coordinate,  $\lambda$  equals 1 and 2 for  $F^*$  and  $M^*$  respectively,  $\phi$  is the fundamental modal shape which was approximated by  $\phi(z) = (z/H)^\beta$  – with  $\beta = 1.5$  whilst taking  $H$  as the height of the tower.

$$\Upsilon^* = \int_0^H \phi(z)^\lambda \Upsilon(z) dz \quad (1)$$

Generalised forces were combined to find the total amount acting on the wind turbines. This is shown in Table 5 for seven levels of wind, including the case in which  $\bar{U}$  equals zero. This table also shows the average estimated ratio  $F_{EQ}^*/F_W^*$ . Earthquake loading dominates for low values of wind velocity, however this condition changes rapidly as the value of  $\bar{U}$  increases. For example when  $\bar{U} = 5 \text{ ms}^{-1}$  earthquake are about twice wind forces whilst when  $\bar{U} = 10 \text{ ms}^{-1}$  earthquake are about half

wind forces. At the point of the design wind speed, earthquake forces are about 12% of wind peak forces.

TABLE 5

Total generalised forces reported in Table 5 were used to determine the dynamic response of the wind turbines listed in Table 4, assuming linear-elastic performance. This was done through the numerical integration of Eq. (2) whose solution is given by Eq. (3).

$$m\ddot{d} + c\dot{d} + kd = p(t) \quad (2)$$

$$d(t) = e^{-\xi\omega_D\Delta t} \left[ \left( d(0) - \frac{p_i}{k} + \frac{2s\xi}{\omega_n k} \right) \cos(\omega_D\Delta t) + \left( \dot{d}(0) + d(0)\xi\omega_n - \frac{p_i\xi\omega_n}{k} + \frac{2s\xi^2}{k} - \frac{s}{k} \frac{\sin(\omega_D\Delta t)}{\omega_D} \right) \frac{p_i}{k} + \frac{s\Delta t}{k} - \frac{2s\xi}{\omega_n k} \right] \quad (3)$$

In Eq. (2) and (3)  $m$ ,  $c$ , and  $k$  represent the system's mass, damping coefficient, and stiffness;  $d(t)$  and  $\dot{d}(t)$  are displacement and velocity of response respectively;  $p(t)$  is the time-varying force;  $p_i$  and  $s$  represent the  $i$ -th force and its gradient, in the context of the numerical integration;  $\omega_n$  and  $\omega_D$  are the undamped and damped frequency whilst  $\xi$  represents the fraction of critical damping. The results of the numerical integration are shown in Table 6.

TABLE 6

The results in Table 6 show a considerable increase of peak displacements for relatively low levels of wind acting on assumed earthquake-resisting structures. For example, when  $\bar{U} = 2.5 \text{ ms}^{-1}$  the estimated increase is of 21%, 35%, and 38% on the towers of 150 m, 200 m, and 250 m tall, respectively, whereas when  $\bar{U} = 5 \text{ ms}^{-1}$  those figures become 114%, 170%, and 219%. This suggests that the combined effect of earthquake and wind load can be significantly higher than those due to earthquakes only, even for relatively low levels of wind. However, infrastructure could also be designed to withstand wind load only in which case earthquake load would have a different level of impact depending on the design wind load. Wind-resisting design is examined more in detail in the following sections.

#### 4. Probabilities associated to wind and earthquake events

Eurocode 1 (European Standard, 2010) associates wind design loads to a 50-year return period whose probability of annual exceedance is  $P_{50} = 0.02$ . The norm also provides Eq. (4) to scale the 10-min design wind velocity,  $\bar{U}_{50}$  for other probability levels.

$$C_{prob} = \left[ \frac{1 - K \cdot \ln(-\ln(1 - p))}{1 - K \cdot \ln(-\ln(0.98))} \right]^n \quad (4)$$

In Eq. (4)  $K$  is a shape parameter that depends on the coefficient of variation of the extreme-value distribution,  $n$  is a constant number,  $C_{prob}$  is the probability factor and  $p$  represents probability. Eurocode 1 recommends  $K = 0.2$  and  $n = 0.5$ .

$$\log_{10}N = a - bM \quad (5)$$

On the other hand, the Gutenberg-Richter law quoted in Eq. (5), establishes a relationship between frequency of earthquake events and their magnitude. In this equation,  $N$  represents the number of events happening within a year, having magnitude  $\geq M$  and  $a, b$  are site-dependent constants. It follows that Eq. (4) and (5) can be used to infer the magnitude of earthquake events associated to probability values ( $P_{EQ}$ ) which, paired with those related to wind ( $P_W$ ), match the standard probability of wind-resisting design i.e.  $P_{EQ} \cdot P_W = 0.02$ . This is shown in Table 7 for a set of randomly selected locations across the world, assuming  $\bar{U}_{50} = 20 \text{ ms}^{-1}$ .

TABLE 7

In Table 7, rows 3 and 1 relate to local average wind speeds and their probability of occurrence as per Eq. (4). Row 4 provides the probability associated to seismic magnitude depending on location. There are five countries listed in Table 7 with their respective value of  $M_s$  which directly links to their probability of occurrence as per Eq. (5). The reason those specific probabilities - quoted in rows 1 and 4 of the Table, have been selected is because their product matches the probability associated to the design wind speed, which according to Eurocode 1 (European Standard, 2010), corresponds to the design wind speed here assumed to be of  $20 \text{ ms}^{-1}$ . Hence these are meaningful combinations derived from the simultaneous occurrence of earthquake and wind events. According to the data shown in Table 7,  $\bar{U} = 10.33 \text{ ms}^{-1}$  would always be exceeded in a year – see rows 1 and 3, whilst  $\bar{U} = 18.92 \text{ ms}^{-1}$  and  $18.05 \text{ ms}^{-1}$  considerably exceed the probability of the design wind speed as reported in row 1.

The joint occurrence of earthquake and wind events listed on each column of Table 7 therefore match the single probability associated to the design wind load, and define a sub-set of multi-hazard scenarios that tend to magnify the strength and ductility demand of wind turbine towers, as discussed in the following section.

## 5. Strength and ductility demands associated to earthquake and wind load

The relationship between strength and ductility determine the performance level of structures. Although such parameterisation is more common in earthquake than wind applications, both earthquake and wind effects can be merged to quantify linear-elastic and plastic structural performance through strength reduction factors, as in Martinez-Vazquez (2017). In the present investigation the strength demands imposed by multi-hazard conditions was quantified in simple terms through the second moment of area that is required to ensure fully-operational conditions of wind energy infrastructure. On a second stage, a map was established between the estimated demands of strength and the corresponding ductility level. This enabled to assess the performance level of the wind turbine towers subject to earthquake and wind joint effects.

### 5.1 Strength Demand

The relationship  $F_{EQ}^*/F_W^*$  provided in Table 5 was taken to find the required section of prismatic steel towers so that the ratio between the maximum displacement and the displacement that induces the yield stress on the base material, match. To that end, wind and earthquake forces were estimated with Eq. (6).

$$F_W^* = \frac{F_{EQ}^* + F_W^*}{F_{EQ}^*/F_W^* + 1} \quad (6a)$$

$$F_{EQ}^* = \frac{F_{EQ}^* + F_W^*}{F_W^*/F_{EQ}^* + 1} \quad (6b)$$

Strength demands across the three wind turbine towers were defined in terms of the ratio  $I_{EQ+W}/I_{EQ \text{ or } W}$ , where  $I_j$  is the second moment of area associated to material yielding, given the load  $j$ . The strength demand associated to design earthquake ( $I_{EQ}$ ) or wind load ( $I_W$ ) is thus magnified when this relationship exceeds 1. Results of this analysis are shown in Table 8 considering two load scenarios: average values associated all 40 earthquake records listed in Table 1 (EQ#1-40), and values characterising isolated events, namely, EQ#5, EQ#24, and EQ#38. All these combinations being consistent with the probability analysis reflected in Table 7. For example, EQ#5 which has a magnitude  $M_s = 5.3$ , would be exceeded every year in earthquake prone areas (Global Data) as it is lower than  $M_s = 6.36$ , therefore it can be combined with any wind event. EQ#24 with  $M_s = 6.53$  can be combined with wind events having  $\bar{U} \leq 18.92 \text{ ms}^{-1}$  whereas EQ#38 with  $M_s = 7.01$  can be combined with wind events having  $\bar{U} \leq 18.05 \text{ ms}^{-1}$ . It is also worth noting that values in Table 8 which are higher than 1 indicate that the multi-hazard condition would exceed the design strength,  $I_{EQ \text{ or } W}$ .

TABLE 8

From Table 8 it becomes apparent that wind turbine towers would primarily be designed to withstand wind load since all values of  $I_{EQ+W}/I_{EQ}$  are above 1 whilst most values of  $I_{EQ+W}/I_W$  are below 1. The sub-set  $18.05 \text{ ms}^{-1} \leq \bar{U} \leq 20 \text{ ms}^{-1}$  however defines a region of magnified strength demands ranging between  $1 \leq I_{EQ+W}/I_W \leq 1.206$ . Note that EQ#24 in Table 8 could not be combined with  $\bar{U} = 20 \text{ ms}^{-1}$  because its magnitude exceeds  $M_s = 6.36$  therefore the combined probability of those events exceeds  $P_{50} = 0.02$ . With the same criteria two other combinations of EQ#38 were discarded. Keeping with wind resisting design, the combined action of  $\bar{U} = 18.92 \text{ ms}^{-1}$  and the average of the set EQ#1-40 would match the strength demand imposed by the design wind load, whereas the demand of strength would be exceeded in 20.6% if the same wind speed did occur simultaneously with an earthquake of  $M_s = 6.53$  (e.g. EQ#24). The latter identifies the worst case scenario as derived from this investigation.

### 5.2 Ductility Demand

In Martinez-Vazquez (2017), a relationship between strength reduction factors ( $R_\mu$ ) associated to multi-load scenarios and structural ductility ( $\mu$ ) is established. The definition of these parameters is given in Eq. (7) and (8) – where  $F$  is the restoring force required to keep inelastic displacements within the limit of the ductility factor  $\mu$  and  $u_y$  is the displacement that limits linear elastic structural performance.

$$R_\mu = \frac{F(\mu=1)}{F(\mu=\mu)} \quad (7)$$

$$\mu = u_{max}/u_y \quad (8)$$

1 In that study  $\Gamma = \frac{M^*}{\sqrt{H^2+W^2+L^2}}$  is defined to characterise the density of structures - where  $M^*$  is the  
2 generalised mass and  $H$ - $W$ - $L$  are side dimensions of prismatic buildings. The relevant strength  
3 reduction factors (SRFs) presented in Martinez-Vazquez (2017) are reproduced here in Fig. 1 and Fig.  
4 2, for cases where  $\bar{U} = 15$  and  $20 \text{ ms}^{-1}$  and when  $\Gamma$  takes values of 1.91, 60.43, and 17.78.  
5  
6

7 **FIGURE 1**

8 **FIGURE 2**

9  
10 For circular shapes, let  $\Gamma = \frac{M^*}{\sqrt{H^2+D^2}}$  - where  $D$  represents the diameter of the steel towers. This  
11 results in  $\Gamma = 2.33 \text{ Ton/m}$ ,  $2.94 \text{ Ton/m}$ , and  $4.17 \text{ Ton/m}$ , for wind turbine towers of 150 m, 200 m,  
12 and 250 m height, respectively. It follows that the magnification of strength demands highlighted in  
13 Table 8 can be expressed in terms of ductility demand, as suggested by Eq. (7) and (8). By  
14 interpolation of the curves shown in Fig. 1 and 2, the average ductility demands estimated across the  
15 three wind turbine towers can be established. This is shown in Table 9.  
16  
17  
18  
19  
20

21 **TABLE 9**

22 The results shown in Table 9 show that the combined action of wind and earthquakes can trigger  
23 inelastic performance of wind turbine towers i.e.  $\mu > 1$ . It is also seen that both strength and  
24 ductility demands equal 1 when  $\bar{U} = 18.92 \text{ ms}^{-1}$  and considering all earthquake records in the  
25 database - noting that this wind speed is lower than the assumed design wind speed  $\bar{U}_{50} = 20 \text{ ms}^{-1}$ .  
26 Furthermore, when the expected earthquake event i.e. EQ#1-40 occurs simultaneous to  $\bar{U}_{50}$  the  
27 strength and ductility demand both exceed a design limited by the yield condition in 12% and 37%  
28 respectively. If particular events such as EQ#5, EQ#24, and EQ#38 are considered, strength demand  
29 exceedances oscillate between 3.2% and 20.6% whilst the associated ductility demands would  
30 surpass the yield condition in amounts ranging 9% to 62%.  
31  
32  
33  
34  
35

## 36 **6. Final Remarks**

37 This research identifies a narrow yet existing probability that earthquake and wind effects modify  
38 the performance level of wind energy infrastructure. The estimated strength and ductility demand of  
39 wind turbine towers indicate that under certain conditions these can undergo unforeseen inelastic  
40 performance during extreme events. This is not addressed by current engineering practice which is  
41 based on the assumption that multi-hazard scenarios are extremely rare and that no relationship can  
42 be established between earthquake and wind events. The evidence however demonstrates that the  
43 frequency of occurrence of earthquakes of medium to high intensity is not rare. According to NOAA  
44 (2017) a total of 1142 earthquakes of  $5.3 \leq M_s \leq 7.01$  occurred across the world in the last 50 years  
45 (1966-2016) with as many as 173 recorded in the last 5 years (2011-2016) and 28 of those in 2016.  
46 The situation depicted in this investigation could be worse if we consider earthquake events of  
47 higher magnitude. NOAA (2017) reports a total of 418 ground motions of  $7.01 \leq M_s \leq 9.9$  in the last  
48 50 years whilst 62 and 11 of those events were seen in the period 2011-2016 and during 2016,  
49 respectively. The recent events recorded in Mexico included two major earthquakes within a period  
50 of two weeks in September 2017 (CNN, 2017) with one of them nearly clashing with hurricane Katia  
51 on 8 September 2017 (ABC News, 2017). This adds further arguments against current design  
52 assumptions which ignore multi-hazard scenarios. It seems therefore necessary to consider regional  
53 risk to extreme events in the formulation of a more robust design framework for practical use.
