30 **Abstract**  
31

32 Strong HfB<sub>2</sub> powder green bodies with compressive strengths exceeding 20  
33 MPa have been produced by incorporating 1 wt% of glassy carbon derived  
34 from a pyrolyzed phenolic resin binder. Starting from the green body after  
35 debinding in argon, non-textured HfB<sub>2</sub> ceramics (diameter ~20 mm and height  
36 ~4 mm) with a relative density of 95.1% were achieved using flash spark  
37 plasma sintering (FSPS) with a discharge time of 20 s, peak power of 19 kW  
38 and applied pressure of ~16 MPa. The lack of a need for a pre-sintering step  
39 resulted in energy savings compared to the densification of HfB<sub>2</sub> ceramics by  
40 FSPS.

62

1 Sintering is an essential step in the production of almost all ceramics; however,  
2 conventionally it is both time and energy intensive. A significant saving in both  
3 factors has been recently realised via “flash sintering (FS)” [1]. This process  
4 involves application of an electric field across a ceramic green body to  
5 promote Joule heating. Under constant voltage mode, a flash event (a sharp  
6 increase in the temperature of the sample) can be triggered when the furnace  
7 temperature exceeds a threshold value. This allows ceramics to be densified  
8 in a matter of seconds [2-3]. A thermal runaway-based model can predict the  
9 heat balance; the flash occurs when the Joule heating significantly exceeds  
10 the heat dissipated to the nearby environment [2-6].

25 Previous investigations, however, have recognised that an inhomogeneous  
26 temperature distribution exists within samples during flash sintering [7]. Such  
27 inhomogeneity is reduced when the green body has a dog-bone shape and  
28 this special geometry is also chosen to maintain a uniform field across the  
29 sample, as well as a volumetric power dissipation [7-8]. To reduce the need  
30 for such a specific geometry requirement, with a cross section limited to a few  
31 square millimetres and sample weight to typically below 1 g, a modified  
32 configuration for FS has been implemented using a spark plasma sintering  
33 (SPS) furnace [9-13]. Various ceramics, including SiC [11], ZrB<sub>2</sub> [9], ZrO<sub>2</sub> [12]  
34 and B<sub>4</sub>C [13], with diameters up to 60 mm have been consolidated by the  
35 flash spark plasma sintering (FSPS) in less than a minute.

53 A green body for a typical FSPS process has to be strong enough to withstand  
54 the thermal stresses resulting from the rapid heating, whilst the compressive  
55 strength also has to exceed the contact force of the SPS apparatus. The latter

1 is required to ensure good electrical contact and so avoid electrical arcing /  
2 overheating at the contacts of the punch-die-ram assembly. Pre-sintering of  
3 the pellets at a relatively low temperature and pressure has been commonly  
4 adopted to obtain a suitably strong body for FSPS; the relative density of the  
5 ceramic body after pre-sintering is normally between 45% and 63.6% [9,12].  
6 For example, ZrB<sub>2</sub> and yttria-stabilized zirconia green bodies were pre-  
7 sintered by SPS at 1600°C / 16 MPa / 20 min [9] and 750°C / 30 MPa / 1 min  
8 [12], respectively. This need clearly reduces the potential advantages of FSPS  
9 in terms of overall time and energy savings.

23 In the present work, the green strength of the ceramics was increased by the  
24 incorporation of 1 wt% of glassy carbon into the ceramic matrix. HfB<sub>2</sub>, a well-  
25 known ceramic that is hard-to-densify [14-16], e.g. hot pressing at 2200°C /  
26 30 MPa for 60 mins only yielded 85.8% of the theoretical density [14], was  
27 used to demonstrate the potential of this method during FSPS.

36 HfB<sub>2</sub> (D<sub>50</sub> = 3.7 μm, C: 0.1 wt%, O: 0.2 wt%, Treibacher, Althofen, Austria) and  
37 2 wt% B<sub>4</sub>C (D<sub>50</sub> = 0.5 μm, H.C. Starck, grade BF-12, Goslar, Germany)  
38 powders were ball mixed together in ethanol for 24 h. In some batches, 2.43  
39 wt% phenolic resin (PR, Hexion Inc., Rotterdam, The Netherlands) was added  
40 into the slurry before mixing [14,15]. The slurry was subsequently dried at  
41 40°C for 0.5 h to remove all the solvent; simultaneous magnetic stirring was  
42 employed in order to avoid any possible sedimentation during drying. The  
43 resulting dried powder cake was crushed into fine powders, which were then  
44 die pressed at 200 MPa into pellets with a diameter of 20 mm and height of 5  
45 mm using a steel mould preheated to 40°C to soften the phenolic resin. The

1 green body was pyrolyzed at 600°C for 2 h in argon using a heating rate of  
2 1°C/min to convert the phenolic resin into carbon. The compressive strength  
3 of the green bodies before and after pyrolysis at 600°C (denoted as P-RT and  
4 P-600) were measured using 5 mm  $\Phi \times 10$  mm height cylindrical samples  
5

12  
13  
14 FSPS runs were conducted in a commercial SPS furnace (FCT HPD 25; FCT  
15 Systeme GmbH, Rauenstein, Germany) under vacuum. The general details  
16 are given elsewhere [11]. The as-pyrolyzed, pressed HfB<sub>2</sub> green bodies were  
17 wrapped with a layer of 4 mm thick graphite felt to avoid the effect of radiative  
18 heat loss as much as possible and to minimize the temperature difference  
19 across the sample during heating. Each sample was placed between the two  
20 graphite punches and a pre-load of 5 kN was applied in order to achieve good  
21 electrical contact. After some initial trials, a maximum power of between 10-20  
22 kW, depending on the discharging time and the relative pre-set power of the  
23 SPS, was chosen. Two discharging times, 20 and 35 s, were finally adopted  
24 whilst the corresponding relative power was set at 100% and 80%,  
25 respectively. During FSPS the temperature was measured using two  
26 pyrometers, one was located at the top of the furnace and focused on the  
27 graphite punch at a distance of 4 mm from the sample, whilst the second was  
28 located on the side of the furnace and focused on the graphite felt covering  
29 the sample.

1 HfB<sub>2</sub>, B<sub>4</sub>C and C. Scanning electron microscopy, SEM (JEOL 7000, Tokyo,  
2 Japan), was used to observe the fracture surfaces of the green bodies as well  
3 as polished surfaces of the sintered bodies. A dual beam FIB / FEG-SEM  
4 equipped with an EBSD detector was employed to look for the evidence of  
5 crystallographic texture in the flash sintered samples. Orientation maps were  
6 obtained from the surfaces perpendicular to the loading direction and the step  
7 size for the EBSD scans was 0.2 μm. A misorientation angle larger than 5°  
8 was used to determine the mean grain size and its distribution in the sintered  
9 ceramics. A 200 kV JEOL TEM (2100F) equipped with electron energy loss  
10 spectrometry (EELS, GIF 963, Gatan, USA) was used to detect the features  
11 and locations of any as-pyrolyzed carbon in the HfB<sub>2</sub> matrix.

28 Without phenolic resin additions, HfB<sub>2</sub> – 2 wt% B<sub>4</sub>C powders could not be  
29 pressed into crack-free pellets. According to the manufacturer, the phenolic  
30 resin used in this work had a pyrolytic carbon (PyC) yield of 41 wt% after  
31 pyrolysis. Using this, the calculated composition in the green body after  
32 pyrolysis was HfB<sub>2</sub> – 2 wt%B<sub>4</sub>C – 1 wt%C. Average compressive strengths of  
33 9.6±0.3 and 20.2±0.7 MPa were measured for P-RT and P-600, respectively.  
34  
35 Since 20 mm diameter samples were used for FSPS, the maximum  
36 compressive load that the P-600 samples could take was ~10 kN. This value  
37 was greater than the minimum load (5 kN) applied by the SPS equipment  
38 during its initial loading.

55 The behaviours of P-RT and P-600 (the relative density of both was ~55%)  
56 under uniaxial compression are compared in Fig. 1a. P-RT shows classic  
57 ductile behaviour, which explains the better shaping behaviour of the powder  
58  
59  
60  
61  
62  
63  
64  
65

1 mixture when PR was present. In contrast, no apparent plastic deformation  
2 prior to failure was observed in P-600 indicating that these samples fractured  
3 in a brittle manner with an enhanced compressive strength value.  
4  
5

6  
7 As may be observed within the backscattered SEM image of P-RT in Fig. 1b,  
8 there were a number of grains with slightly darker contrast that were well  
9 distributed within the HfB<sub>2</sub> matrix. The average HfB<sub>2</sub> primary particle size from  
10 Fig.1b is 1.25 μm, significantly smaller than the D<sub>50</sub> value (3.7 μm) provided  
11 by the manufacturer, indicating agglomeration existed in the raw powders.  
12  
13 Considering that the mean atomic numbers of both PR and B<sub>4</sub>C are much  
14 smaller than for HfB<sub>2</sub>, these darker grains must be either PR or B<sub>4</sub>C. The EDS  
15 analysis results shown in Fig. 1d & e revealed that point A is PR whilst point B  
16 is B<sub>4</sub>C. The oxygen and carbon signals in PR, Fig. 1d, are much stronger than  
17 those in B<sub>4</sub>C, Fig. 1e. After pyrolysis, flakes with thickness less than 100 nm  
18 were observed occasionally on the fracture surface of P-600; highlighted by  
19 arrows in Fig. 1c. It seems that these nanostructures were derived from the  
20 pyrolysed PR. Previous work has shown that the densification of HfB<sub>2</sub> by hot  
21 pressing starts above 1650°C [14], therefore, the strength improvement in P-  
22 600 compared to P-RT cannot be ascribed to partial sintering since the heat  
23 treatment only occurred at 600°C. As a result, the different behaviour under  
24 compression between P-RT and P-600 must be due to the conversion from  
25 PR to PyC. To illuminate this further, the bonding characteristics between the  
26 PyC and HfB<sub>2</sub> particles were further investigated using TEM to explain the  
27 strengthening mechanism found in the P-600 samples.

1 Fig. 2a clearly shows two HfB<sub>2</sub> particles connected by a nanosheet stack.  
2 Although these sheets exhibit a layered structure, no clear lattice fringes could  
3 be observed from their basal plane, Fig. 2b. In an enlarged view of the  
4 junction between the nanosheets and HfB<sub>2</sub> grains, Fig. 2c, some particles less  
5 than 5 nm in size but with good crystallinity were found. Some of the  
6 interplanar spacings of these particles are shown in Fig. 2c; some fit with B<sub>4</sub>C  
7 (4.50, 3.78 and 2.37 Å), whilst the others (3.36 and 3.37 Å) are similar to the  
8 (0002) spacing of graphite (3.38 Å). The nanosheets not only bridge the  
9 adjacent particles, arrowed in Fig. 2a and 2e, they also coat the surface of  
10 some of the HfB<sub>2</sub> grains, as revealed by the HRTEM image in Fig. 2d.

26 According to the EELS maps of carbon and boron, Fig. 2g & h, a layer only  
27 containing carbon, region I in Fig. 2h, was observed to cover the edge of an  
28 HfB<sub>2</sub> particle, arrowed in Fig. 2f. Between the carbon layer and the HfB<sub>2</sub>  
29 particle, region III in Fig. 2h, an ~50 nm transition zone was observed  
30 composed of B and C, region II in Fig. 2h. The bonding between the carbon  
31 and HfB<sub>2</sub> appears to be quite strong since the carbon coating seems to be  
32 chemically anchored.

46 Ionisation edges corresponding to C-k were also found in the EELS patterns  
47 of the nanosheets, which show two peaks centred at about 287 and 298 eV,  
48 respectively, Fig. 2i. The first sharp peak belongs to the transitions of the π\*  
49 molecular orbital due to the existence of sp<sup>2</sup> bonded carbon, whilst the second  
50 more intense peak at 298 eV was induced by the σ\* orbitals transitions of  
51 carbon [17]. The slight broadening of the latter peak is a characteristic for

glassy carbon; in amorphous carbon it is normally significantly broader compared to glassy carbon [17]. Glassy carbon is a non-graphitic carbon mainly constituted of  $sp^2$  bonded atoms. It can exist as clusters or ribbons of graphite-like sheets interspersed with regions of amorphous carbon [18]. Both the EELS and HRTEM observations in Fig. 2 suggest that the PyC flakes derived from the PR are likely to be glassy carbon, which has a relatively high modulus of ~30 GPa and flexural strength of ~190 MPa [19]. If correct, both the bridging and coating of glassy carbon nanosheets on the  $HfB_2$  particles will have been responsible for the higher strength in the P-600 compared to the P-RT.

The change in the sintering parameters during FSPS, including electrical resistance, displacement, electric current, SPS heating power and resulting front pyrometer temperature, are shown in Fig. 3. When a sample with an electrical resistance of  $R$  is subjected to a voltage of  $V$ , the sample heating rate ( $dT/dt$ ) may be expressed as Eq.1 [5].

$$\frac{dT}{dt} = \frac{1}{C} \left[ \frac{V^2}{R(T)} - \varepsilon\sigma(T^4 - T_f^4) \right] \quad (1)$$

Where  $C$  and  $\varepsilon$  represent the sample's heat capacity and emissivity,  $\sigma$  is the Stefan–Boltzmann constant,  $T$  and  $T_f$  are the temperature for the sample surface and furnace, respectively. It should be noted that Eq.1 is not strictly applicable to current FSPS set-up as it neglects the Joule heating of the carbon felt and its low thermal conductivity. Unlike most oxides [2,6], the electrical resistance of metal diborides such as  $HfB_2$  increases linearly with temperature [20]. Therefore,  $dT/dt$  will decrease when a constant voltage is

1 applied to HfB<sub>2</sub>-based samples and flash heating (an exponential increase in  
2 heating rate) will not occur without an additional sharp increase in the voltage.  
3  
4

5  
6  
7 As has been discussed previously [11], at the beginning of FSPS the current  
8 preferentially passed through the carbon felt, as shown by the initial  
9 temperature increase recorded by the front pyrometer (T<sub>f</sub>), Fig. 3a. This  
10 effectively caused the samples to be preheated. Subsequently, the current  
11 began to flow through the sample, leading to a drop in T<sub>f</sub> and a simultaneous  
12 decrease in electrical resistivity for the circuit, Fig. 3a. When the discharge  
13 began, a simultaneous increase in displacement and the top temperature, T<sub>t</sub>,  
14 was observed, Fig. 3a. The densification behaviour of HfB<sub>2</sub> ceramics during  
15 FSPS was strongly depending on the flash; Fig. 3b shows that a shorter  
16 discharge time and higher relative power was helpful in causing a more  
17 obvious flash and, consequently, an enhanced shrinkage rate. The porosity of  
18 the HfB<sub>2</sub> decreased to <5 vol% when discharge occurred in 20 s, whilst when  
19 it took 35 s the porosity did not decrease below 20 vol%, Fig. 3b.

41 Most of the HfB<sub>2</sub> samples sintered using FSPS were crack-free in this work,  
42 Fig. 3e. A mean relative density of 95.1% was obtained for the ceramics  
43 densified using a discharge time of 20 s and a relative power of 100%.  
44 Residual pores can be clearly seen, they are visible as dark regions with  
45 slightly bright edges from charging and are highlighted in some cases by  
46 arrows in Fig. 4a. Other areas with a dark contrast indicate B<sub>4</sub>C and carbon  
47 grains. Both pores and B<sub>4</sub>C grains are mainly located at the grain boundaries,  
48 as shown in the grain orientation map, Fig. 4b. The latter also confirms that no

1 texturing was generated during densification. The average HfB<sub>2</sub> grain size in  
2 the sintered bodies was ~4 μm, Fig. 4c, slightly larger than that of the reported  
3 average particle size of 3.7 μm. This value is much larger than the primary  
4 particle size of HfB<sub>2</sub> in the green body determined by SEM, ~1.25 μm,  
5 indicating densification and grain growth still compete with each other during  
6 FSPS as in conventional sintering. The final microstructure had equiaxed  
7 morphology with an average aspect ratio of ~1.2 for the HfB<sub>2</sub> grains, Fig. 4d.  
8 The number of neighbouring grains calculated, Fig. 4e, fits a normal  
9 distribution and the average value is close to six. Although the HfB<sub>2</sub> ceramics  
10 were rapidly densified in only 20 s during FSPS, the resultant microstructures  
11 still resembled those sintered more conventionally. Based on the calculations  
12 in Table 1, by utilizing a proper design and optimization process for the green  
13 forming, the energy cost of FSPS could be further reduced by up to 80%,  
14 compared to FSPS using normal pre-heating.

36 In summary, starting with coarse HfB<sub>2</sub> powder, >95% dense HfB<sub>2</sub> ceramics  
37 were achieved by FSPS in a discharge time of just 20 s, using 2 wt% B<sub>4</sub>C and  
38 1 wt% C as sintering aids. This work also demonstrates that pre-sintering,  
39 which is routinely adopted for flash SPS, is not necessary if ceramic green  
40 bodies strengthened by the presence of 1 wt% of glassy carbon are used.
