**Abstract:** AISI 304 austenitic stainless steel was low-temperature liquid nitrided in a molten salt bath at 703 K for 8 h, which produced a 3-layered structure consisting of a top oxide layer, an intermediate nitrogen-rich layer and a bottom carbon-rich layer. The effect of nitriding on its corrosion resistance was investigated in a H<sub>2</sub>S environment. The corrosion rate of the untreated sample is about 3.3 times that of the nitrided sample after H<sub>2</sub>S corrosion. Corrosion pits can be clearly observed on the surface of the untreated sample, while the nitrided sample surface remained relatively intact. Both the oxide layer and the nitrogen-rich layer can help reduce the hydrogen permeation, which is beneficial for combating hydrogen embrittlement. The corrosion products mainly consisted of oxides, hydroxides, and sulfates. The nitrided layers can serve as a barrier to corrosion, thus preventing the corrosion of the substrate material. Active nitrogen in the nitrided layer reacts with H<sup>+</sup> ions to form NH<sub>4</sub><sup>+</sup>, which effectively prevents further acidification of the local area and inhibits the occurrence of pitting corrosion and the dissolution rate of the metal in the etching hole, thus improving the local corrosion resistance of the stainless steel.

**Key words:** austenite stainless steels, expand austenite, corrosion resistance, liquid nitriding, surface treatment

## 1. Introduction

Austenite stainless steel is widely used in various industrial fields due to its excellent corrosion resistance and mechanical properties. With the increasing exploitation and processing of high sulfur oil and gas field, H<sub>2</sub>S corrosion has become a widespread concern.<sup>[1]</sup> H<sub>2</sub>S is one of the most dangerous factors causing metal corrosion in acidic oil and gas environments, and electrochemical corrosion will occur on the surface of the pipeline used.<sup>[2]</sup> In recent years, many researchers have conducted extensive research on the local corrosion and stress corrosion cracking (SCC) mechanism of stainless steel in H<sub>2</sub>S medium. The research was focused on the

40 structure, properties, formation process and external factors of corrosion products in  
41 saturated H<sub>2</sub>S systems.<sup>[3-6]</sup> Ding et al. investigated the behavior of corrosion and SCC  
42 of austenitic stainless steels in high H<sub>2</sub>S–CO<sub>2</sub>–Cl<sup>-</sup> environments. <sup>[7]</sup> Their results  
43 showed that high H<sub>2</sub>S–CO<sub>2</sub> pressure can accelerate anodic dissolution process,  
44 deteriorate passive films, and aggravate SCC sensitivity. The corrosion rate of steel in  
45 wet H<sub>2</sub>S is significantly higher than that in dry H<sub>2</sub>S environment.<sup>[8]</sup> H<sub>2</sub>S reacted with  
46 metals to form surface metal sulfides, and released hydrogen atoms, which were  
47 absorbed by the metal surface and caused hydrogen embrittlement.<sup>[9]</sup> Besides, low pH  
48 can promote both cathodic and anodic actions on stainless steel and facilitate passive  
49 film breakdown.<sup>[7]</sup>

50 In addition to the corrosion of H<sub>2</sub>S, CO<sub>2</sub> and Cl<sup>-</sup>, saturated natural gas in  
51 pipelines will have a free liquid phase due to the effect of pressure drop, and a certain  
52 amount of solid impurities will be mixed in the pipeline, resulting in three-phase  
53 coexistence of gas, solid, and liquid. Erosion-corrosion is faster than corrosion alone  
54 and is a more hazardous local corrosion.<sup>[10]</sup> When corrosive liquid contains solid  
55 particles (such as insoluble salts, sand, drilling fluid, etc.), it is more likely to cause  
56 such erosion-corrosion damage. Austenitic stainless steels have a low carbon content  
57 (mass fraction below 0.03 %), resulting in a low surface hardness and poor wear  
58 resistance. The service life of stainless steel pipes under such conditions will be  
59 seriously reduced, and so it is necessary to improve their surface hardness and  
60 strength on the premise of ensuring its good comprehensive performance.

61 It has been reported previously that austenitic stainless steels are  
62 thermochemically treated (carburized or nitrided) at low temperatures to form  
63 interstitial atoms supersaturated non-deposition layers. <sup>[11-12]</sup> After the treatment, a  
64 layer with a high concentration of nitrogen and/or carbon will be formed on the  
65 surface of the treated austenitic stainless steel. This surface layer can effectively  
66 improve the hardness, wear resistance, fatigue resistance and corrosion resistance of  
67 the material, which is so-called S-phase or expanded austenite.<sup>[12]</sup> Low-temperature  
68 nitriding has been shown to significantly improve pitting potential. Dong discovered  
69 that low temperature nitrided 316 stainless steel showed excellent resistance to pitting  
70 of chlorine containing solution, and the increased corrosion resistance of the nitride S  
71 phase layer is thought to be due to its high nitrogen content.<sup>[13]</sup> The enhancement in  
72 corrosion resistance of austenitic stainless steels by nitriding or carbonization  
73 treatment may be related to a high surface interstitial atom concentration or a large  
74 surface residual compressive stress due to interstitial atoms.<sup>[14]</sup>

75 Zhang et al. performed Quench-Polish-Quench (QPQ) salt bath compound  
76 treatment on GX-8 alloy steel and found that the dense oxide film Fe<sub>3</sub>O<sub>4</sub> could  
77 significantly reduce the friction coefficient of the material at 573 K, and the corrosion  
78 resistance of the material was greatly improved before the oxide film was ruptured.<sup>[15]</sup>  
79 However, the QPQ treatment is a multi-step and hence relatively complicated process.  
80 In contrast, low-temperature salt bath nitriding does not require an additional  
81 oxidation process to form a surface oxide layer. Hence, the salt bath nitriding process  
82 is simpler and the cost of the equipment is lower than the QPQ process.

83 The aim of the present paper was to study the effect of low-temperature liquid

84 bath nitriding on the corrosion resistance of AISI 304 austenitic stainless steel in a  
85 H<sub>2</sub>S containing environment. Through the H<sub>2</sub>S immersion corrosion tests, the  
86 corrosion behavior and the corrosion mechanism of low temperature salt bath nitride  
87 304 austenitic stainless steel in H<sub>2</sub>S containing environments (such as pipelines for oil  
88 and gas applications) were studied. The low-temperature nitriding is expected to be  
89 applied to the pipelines used for oil-gas fields, significantly extending their service  
90 life in the H<sub>2</sub>S corrosion environment.

91

## 92 **2. Experimental**

### 93 2.1 Material

94 The material used in this experiment was cast 304 stainless steel, taken from the  
95 natural gas valve castings supplied by Southwest Natural Gas Research Institute ,  
96 China. The chemical composition provided by the materials supplier is shown in  
97 Table 1. The samples were ground with abrasive papers from 400# down to 1200#,  
98 degreased with a mixture of 50 vol% ethanol and 50 vol% acetone, and finally  
99 washed with deionized water and dried in atmosphere.

100

101

**Table 1** Chemical composition of AISI 304 stainless steel (mass%)

Element	C	Cr	Ni	Mn	Si	S	P	Fe
Pct	0.035	18.640	8.010	1.100	0.436	0.020	0.013	Balance

### 102 2.2 Liquid bath nitriding and H<sub>2</sub>S corrosion test

103 The chemicals used in this experiment for liquid bath nitriding were non-toxic  
104 cyanate, chloride and carbonate salts. The nitriding process involved immersing the  
105 sample in 703 K molten salt for 8 hours, during which the non-toxic cyanate  
106 decomposes into carbon atoms and nitrogen atoms, forming a high chemical potential  
107 on the surface of the samples. More details can be found in literature.<sup>[16]</sup> This high  
108 chemical potential promotes the diffusion of the nitrogen and carbon atoms into the  
109 austenitic stainless steel sample, thus forming a large supersaturation of N(C) in its  
110 surface.

111 H<sub>2</sub>S corrosion tests were conducted in accordance with NACE TM0177-2005  
112 standard using the solution ‘A’ recommended by NACE TM0177-2005. Both the  
113 untreated and nitrated samples were soaked in this solution for 720 hours.

114 Before the H<sub>2</sub>S corrosion test, the mass of the sample (m) was weighed and  
115 recorded. At the end of the test, the corroded sample was taken out, and the corrosion  
116 product formed on the surface was removed with an acid stripping solution (500 ml  
117 HCl + 500 ml H<sub>2</sub>O + 3.5 g C<sub>6</sub>H<sub>12</sub>N<sub>4</sub>). The sample was degreased with acetone and  
118 then dried in a box. After drying for 24 hours, the sample was taken out for weighing  
119 (m<sub>t</sub>), and the corrosion rate was calculated based on the weight loss during the test.  
120 The uniform corrosion rate (R<sub>corr</sub>) is calculated as follows:  
121  $R_{corr}=8.76 \times 10^4 \times (m-m_t)/(S_1 \times \rho \times t)$ , where S<sub>1</sub> is the total area of the test piece (32 cm<sup>2</sup>);  
122 ρ is the density of the test piece material (7.9 g/cm<sup>3</sup>); and t is the test time (720 h).

## 123 2.3 Hydrogen permeation test

124 Hydrogen permeation testing was performed in line with ASTM G148 standard  
125 using a type Avanathan-Stachursky double-electrolytic cell produced by Wuhan  
126 Corrtest, China.<sup>[17]</sup> Three sets of samples were prepared: untreated samples,  
127 as-nitrided samples and the nitride samples whose surface oxide film was removed by  
128 mechanical polishing. The samples used in this test were stainless steel wafer  
129 electrodes with a working surface of 1.77 cm<sup>2</sup> and a thickness of 0.2 mm. The  
130 experimental conditions were decided by referring to literature.<sup>[18-19]</sup> The experimental  
131 solution is 0.5 mol/L sulfuric acid with 1 g/L CH<sub>4</sub>N<sub>2</sub>S, and the hydrogen charge  
132 current is 20 mA/cm<sup>2</sup> with an anode potential of 300 mV. Before the test solution was  
133 added, the sample was passivated in a 0.2 mol/L NaOH solution for more than 24 h, in  
134 order that the background current density is less than 0.1 μA/cm<sup>2</sup>.<sup>[20]</sup>

135 The hydrogen diffusion flux ( $J_{\infty}$ ) is calculated from the anode steady-state current  
136 ( $I_{\infty}$ ) and can be expressed as:

$$137 J_{\infty} = \frac{I_{\infty}}{A} \quad [21]$$

138 Where: A is the area of the sample in contact with the solution; F is the Faraday  
139 constant.

140 The effective hydrogen diffusion coefficient ( $D_{\text{eff}}$ ) can be calculated using the formula  
141 below:

$$142 D_{\text{eff}} = \frac{J_{\infty}^2}{I_{\text{a}}^2} \quad [22]$$

143 Where: t is the thickness of the sample;  $t_L$  is the delay time. The delay time is  
144 approximately equal to the time taken for the hydrogen charging current density to  
145 reach 0.63 times the steady-state anode current density, i.e. the time used for  
146  $I_{\text{a}} = 0.63I_{\infty}$ . The hydrogen concentration  $C_0$  at the hydrogen end can be estimated by  
147 the following formula:

$$148 C_0 = \frac{J_{\infty}^2}{D_{\text{eff}}} \quad [22]$$

## 149 2.4 Microstructural characterization

150 The cross section of the sample before and after the H<sub>2</sub>S corrosion tests was  
151 mechanically polished and chemically etched with an etchant formulated with 50  
152 vol% HCl, 25 vol% HNO<sub>3</sub>, and 25 vol% H<sub>2</sub>O. The OLYMPUS GX51 optical  
153 microscope and JSM-7500F scanning electron microscope were used for  
154 microstructural analysis. The surface phases were studied using the EMPYREAN  
155 X-ray diffractometer (XRD) with a scanning range of 20 to 110 degrees with Cu K $\alpha$   
156 radiation ( $\lambda = 0.15418\text{nm}$ ). The SHIMADZU-1720 electron probe microanalyzer  
157 (EPMA) was used to quantitatively analyze the elemental distribution from the  
158 surface to the matrix. X-ray photoelectron spectroscopy (XPS) was used to analyze  
159 the surface corrosion products.

## 160 3. Results

### 161 3.1 Characteristics of the nitrided layers

**Fig.1** A typical cross sectional SEM image of nitrided sample

162  
163  
164

165 Figure 1 shows the cross-sectional photomicrograph of the AISI304 austenitic  
166 stainless steel after low-temperature salt bath nitriding treatment. The substrate shows  
167 clear grain boundaries after etching with the etchant. The salt bath nitriding produced  
168 a 3-layered structure consisting of an oxide top layer, followed by a nitrogen-rich  
169 layer and a carbon-rich layer. The atomic nitrogen was formed from the following  
170  $\text{CNO}^-$  dissociation reaction:  $4\text{CNO}^- \rightarrow 2\text{CN}^- + \text{CO}_3^{2-} + \text{CO} + [\text{N}]$ . Carburizing is also  
171 promoted by the liberation of atomic carbon species according to the following CO  
172 dissociation reaction:  $\text{CO} \rightarrow \text{CO}_2 + [\text{C}]$ . Under the same treatment conditions, the  
173 thickness of the nitrided layer is larger than that of the carburized layer. This is mainly  
174 due to the fact that the atomic radius of N is smaller than that of the C atom, and the  
175 energy required for N atoms to enter the lattice is smaller than that for C atoms. Under  
176 the same conditions, the nitrogen atoms can diffuse deeper than carbon atoms.  
177 Tsujikawa et al. used simultaneous carburizing and nitriding process to obtain a  
178 similar layer on the surface of austenitic stainless steel.<sup>[23]</sup> Due to the long processing  
179 time, certain Cr nitrides appear in the nitrided layer.

### 180 3.2 Corrosion morphology and corrosion rate

181 Nitrided samples and as-received 304 samples were immersed in  $\text{H}_2\text{S}$  solution  
182 for 720 h and the cross-sectional micrographs are shown in the Figure 2.

183 As shown in Figure 2(a), a number of pits and cracks were observed from the  
184 cross-section of the untreated sample, which indicates pitting and cracking of the  
185 sample. In the process of crack propagation, the width and depth of the crack  
186 continuously increased, and the outer layer material eventually spalled off. In contrast,  
187 neither pits nor cracks were observed from the cross-section of the nitrided samples  
188 after  $\text{H}_2\text{S}$  corrosion test (Fig.2(b)).

189

190 **Fig.2** Cross-sectional optical micrographs (OM): (a) untreated sample (b) nitrided sample after  
 191 immersion in H<sub>2</sub>S solution for 720h

192 Figure 3 shows the surface morphology of the untreated and nitrided samples after  
 193 immersion in H<sub>2</sub>S solution for 720h. Many agglomerates were formed on the surface  
 194 of the untreated sample (Fig.3(a)), which is generally considered to be corrosion  
 195 product FeS. The surface of the nitrided sample remained intact as evidenced by the  
 196 existence of the original grinding marks with almost no corrosion product (Fig.3(b)).

197

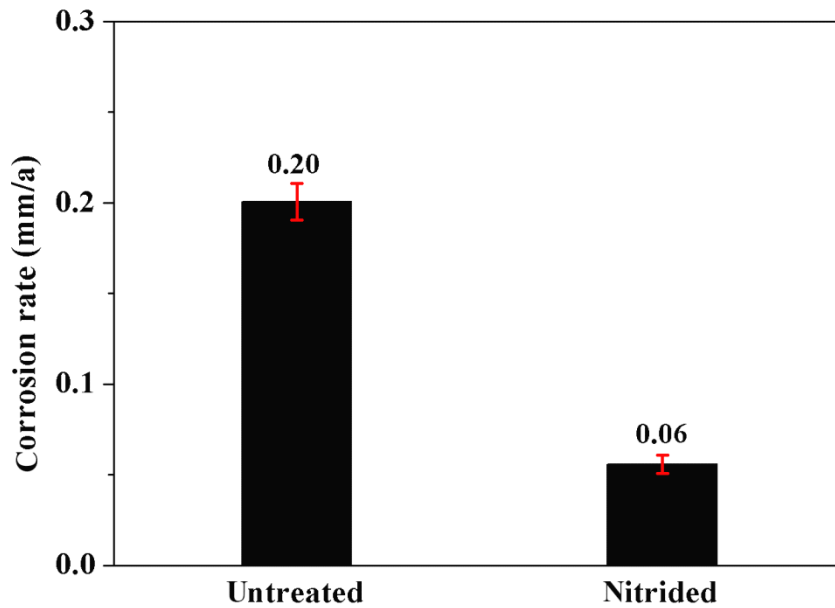

198 **Fig.3** SEM surface corrosion morphology: (a) untreated sample (b) nitrided sample after  
 199 immersion in H<sub>2</sub>S solution for 720h

200 As shown in Figure 4, the corrosion rate of the untreated 304 austenitic stainless  
 201 steel (0.20 mm/a) is approximately 3.3 times that of the nitrided samples (0.06 mm/a).  
 202 This indicates that the nitriding treatment can significantly improve the corrosion  
 203 resistance of 304 stainless steel in the H<sub>2</sub>S environment.

204

205

206

**Fig.4** Corrosion rate after H<sub>2</sub>S corrosion for 720h

207

208

209

210 The ionization of H<sub>2</sub>S in the solution produced a large amount of H<sup>+</sup>, which led to  
 211 a significant decrease in the pH of the solution. The ionization reaction can be  
 212 described as follows: H<sub>2</sub>S = H<sup>+</sup> + HS<sup>-</sup> ; 2HS<sup>-</sup> = 2H<sup>+</sup> + S<sup>2-</sup>. The ionized H<sup>+</sup> is a strong  
 213 depolarizer that can easily take away electrons from the metal and promote the  
 214 dissolution reaction of the anode steel to cause metal corrosion. The process of  
 215 electrochemically etching the cathode and the anode by H<sub>2</sub>S is as follows:

216 Cathode: Fe - 2 e<sup>-</sup> → Fe<sup>2+</sup>;

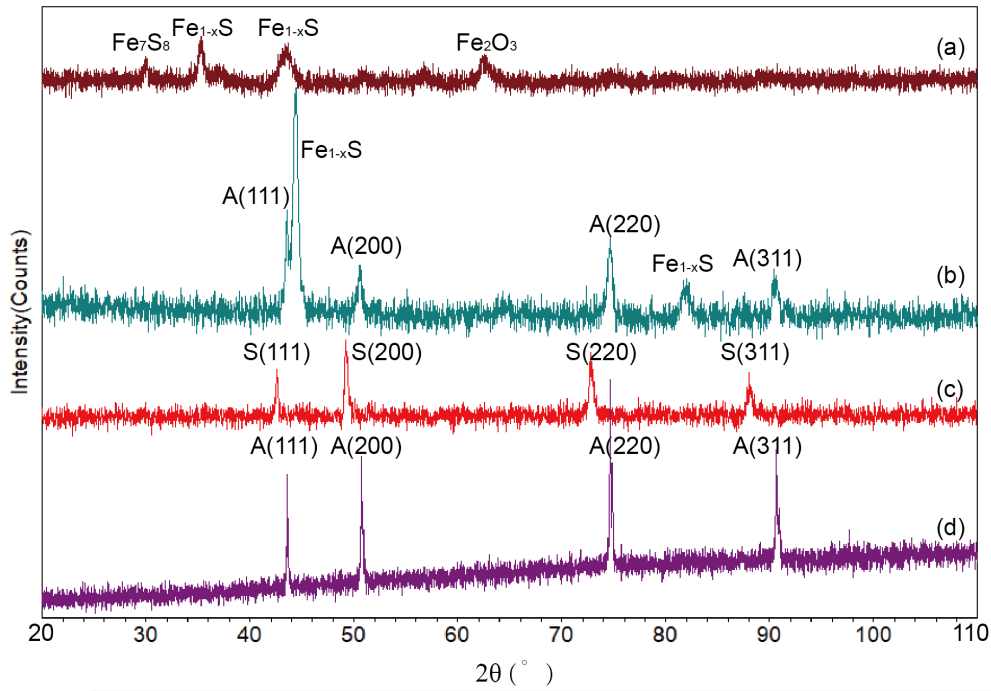

217 Anode: 2H<sup>+</sup> + 2e<sup>-</sup> → 2H → H<sub>2</sub> ↑.

218 The anode corrosion product is: Fe<sup>2+</sup> + S<sup>2-</sup> = FeS↓. Therefore, after the steel is  
 219 corroded by H<sub>2</sub>S, the final product of the anode is FeS. The product usually has a  
 220 defective structure with poor adhesion to the surface of steel. Hence, it can be easily  
 221 detached and oxidized, and has a more positive potential. The corrosion product then  
 222 acts as a cathode and the matrix to form an active microbattery and continues the  
 223 corrosion of the steel. The process repeated itself and the layer eventually cracked.

224

### 225 3.3 XRD analysis

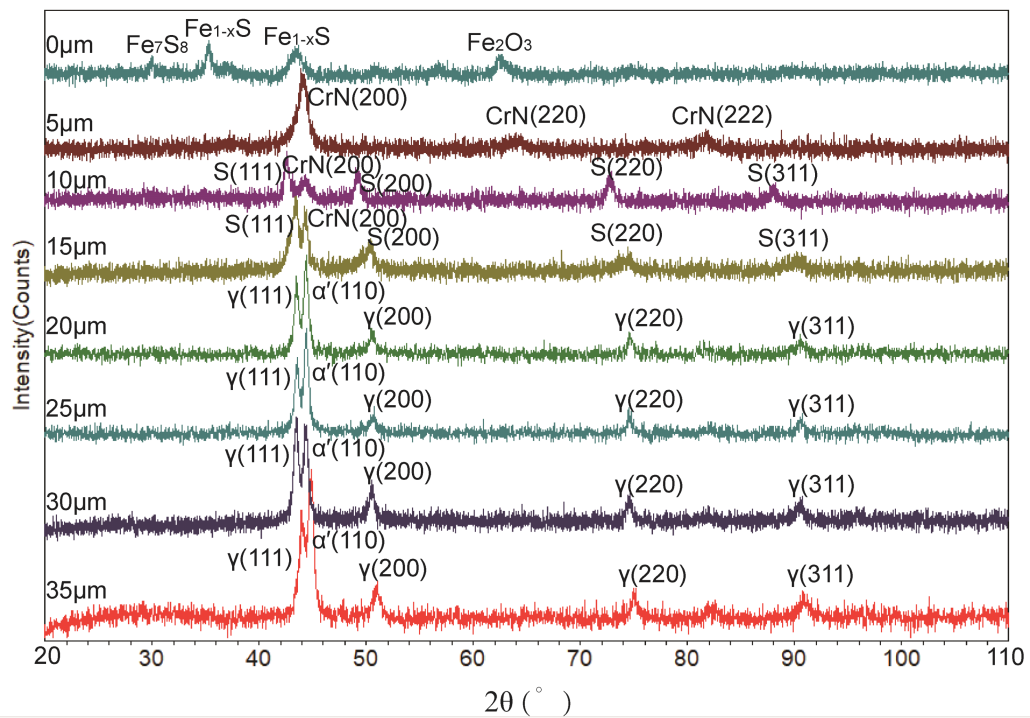

226

227

**Fig.5** XRD patterns for different samples: (a) nitrided sample after corrosion test, (b) untreated sample after corrosion test, (c) as-nitrided sample and (d) untreated sample before corrosion test

228

229

230

231

**Fig. 6** XRD patterns as a function of the depth below the original nitrided surface (after mechanical material removal).

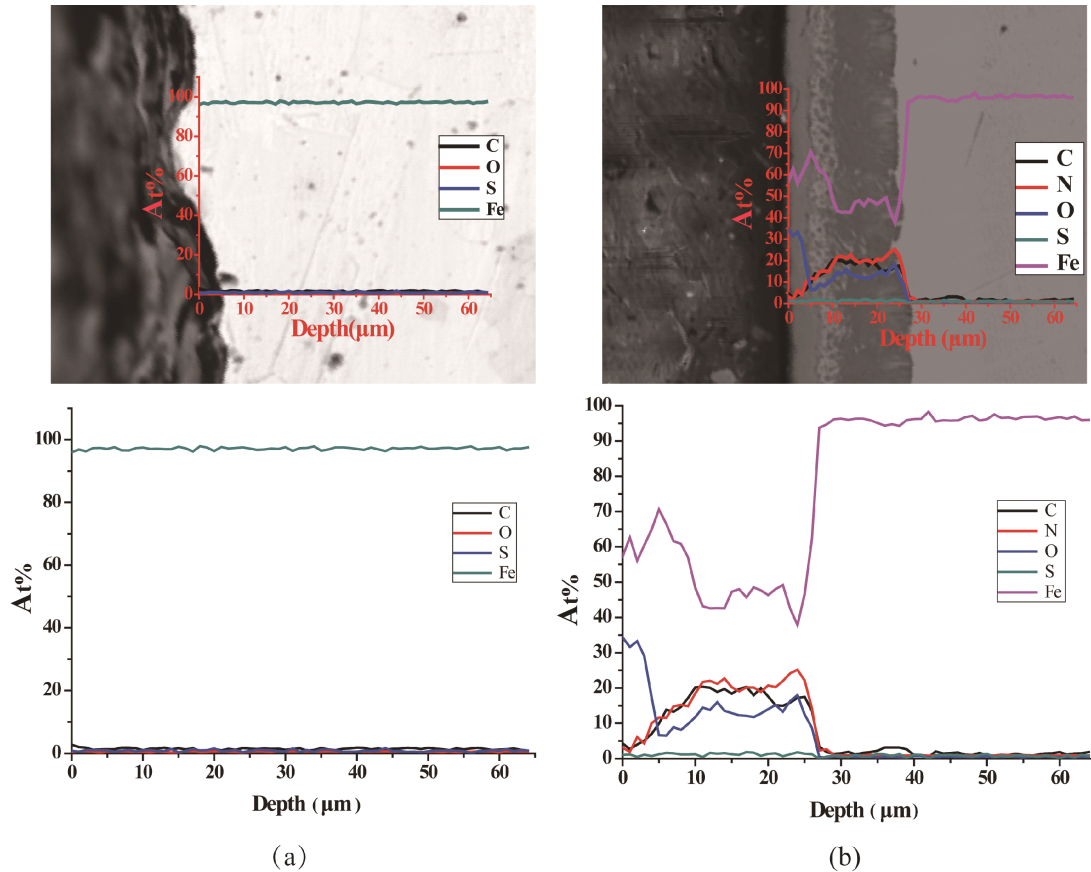

232

233 Untreated and nitrided samples were characterized by XRD to identify the  
234 phases produced as a consequence of H<sub>2</sub>S corrosion process; the diffraction patterns  
235 of the samples are shown in Figure 5. It can be seen from Figure 5 that the untreated  
236 sample shows typical peaks for austenite (Fig.5(d)); the nitrided sample clearly shows  
237 S1(111)、S2(200)、S3(220) and S4(311) peaks. This indicates that the S-phase layer  
238 has been successfully produced during nitriding. The N or C atoms dissolved in  
239 austenite caused the expansion of the original face-centered cubic lattice of austenite  
240 (i.e. expanded austenite) and the left-shift of these peaks.<sup>[24]</sup> As shown in Figure 5(b),  
241 the corrosion product formed on the untreated sample is Fe<sub>1-x</sub>S, which shows two  
242 peaks, one near  $\gamma$ (111) and the other between  $\gamma$ (200) and  $\gamma$ (311). Clear austenite  
243 characteristic peaks can still be observed on the XRD diffraction pattern of the  
244 untreated sample after H<sub>2</sub>S corrosion. The corrosion products of the nitrided samples  
245 were mainly Fe<sub>7</sub>S<sub>8</sub>, Fe<sub>1-x</sub>S, and Fe<sub>2</sub>O<sub>3</sub>. Compared with the untreated samples, the  
246 characteristic peaks of the expanded austenite could not be observed. This implies that  
247 the nitrogen concentrations in the  $\approx 5 \mu\text{m}$  thick layer below the specimen surface that  
248 is sampled by the X-rays would be reduced during the H<sub>2</sub>S corrosion test.

249 The XRD patterns obtained at different depths below the original surfaces are  
250 shown in Figure 6. In the depth of 5  $\mu\text{m}$ , the nitrided sample exhibits three main  
251 diffraction peaks of CrN, which was formed as a consequence of the temperature of  
252 the treatment, the chromium-rich alloy AISI 304, and the high nitrogen content. When  
253 the nitrogen content gradually decreased with the depth, the intensity and the number  
254 of CrN peaks reduced accordingly. Normally, when the AISI 304 stainless steel is  
255 nitride at 703 K or below, the nitrided layer should be free of nitrides. However, the  
256 as-cast 304 stainless steel used in this research may not be well annealed after cold  
257 rolling, and a large amount of deformed martensite ( $\alpha'$ ) was left in the matrix, as  
258 evidenced by the clear  $\alpha'$  peak detected from the substrate (Fig. 6). This resulted in  
259 rapid nitrogen diffusion and precipitation of CrN. At the depth of 10 and 15  $\mu\text{m}$ ,  
260 distinct peaks of S phase and a weak CrN peak can be detected. Then, the  
261  $\alpha'$ -martensite phase was detected from the depth 20  $\mu\text{m}$  down to the substrate, which  
262 is also contributed by the strain-induced martensite formed during the layer-by-layer  
263 mechanical polishing process. Starting from the depth of 20 $\mu\text{m}$ , as the interstitial atom  
264 concentration gradually decreased, the lattice distortion also gradually decreased, and  
265 it is better to call it  $\gamma$ -phase instead of S-phase. The content of interstitial atoms (C  
266 N) continuously decreased with the depth and the diffraction angle of the  $\gamma$ -phase  
267 gradually returned to normal values.

### 268 3.4 EPMA analysis

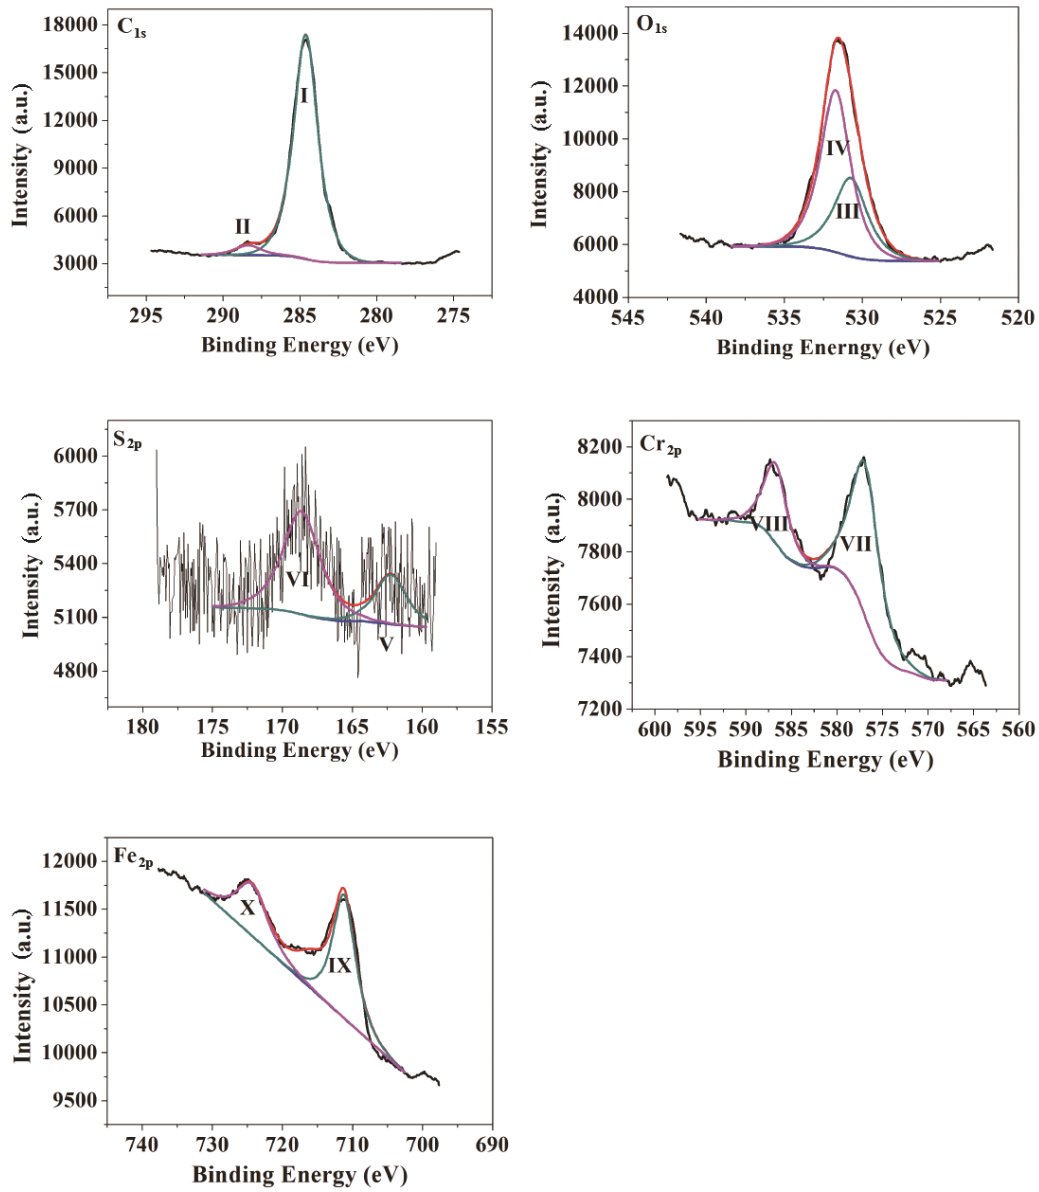

269

270  
 271 **Fig.7** EPMA results of untreated (a) and nitrided samples (b) after immersion corrosion test in  
 272 Solution A for 720h

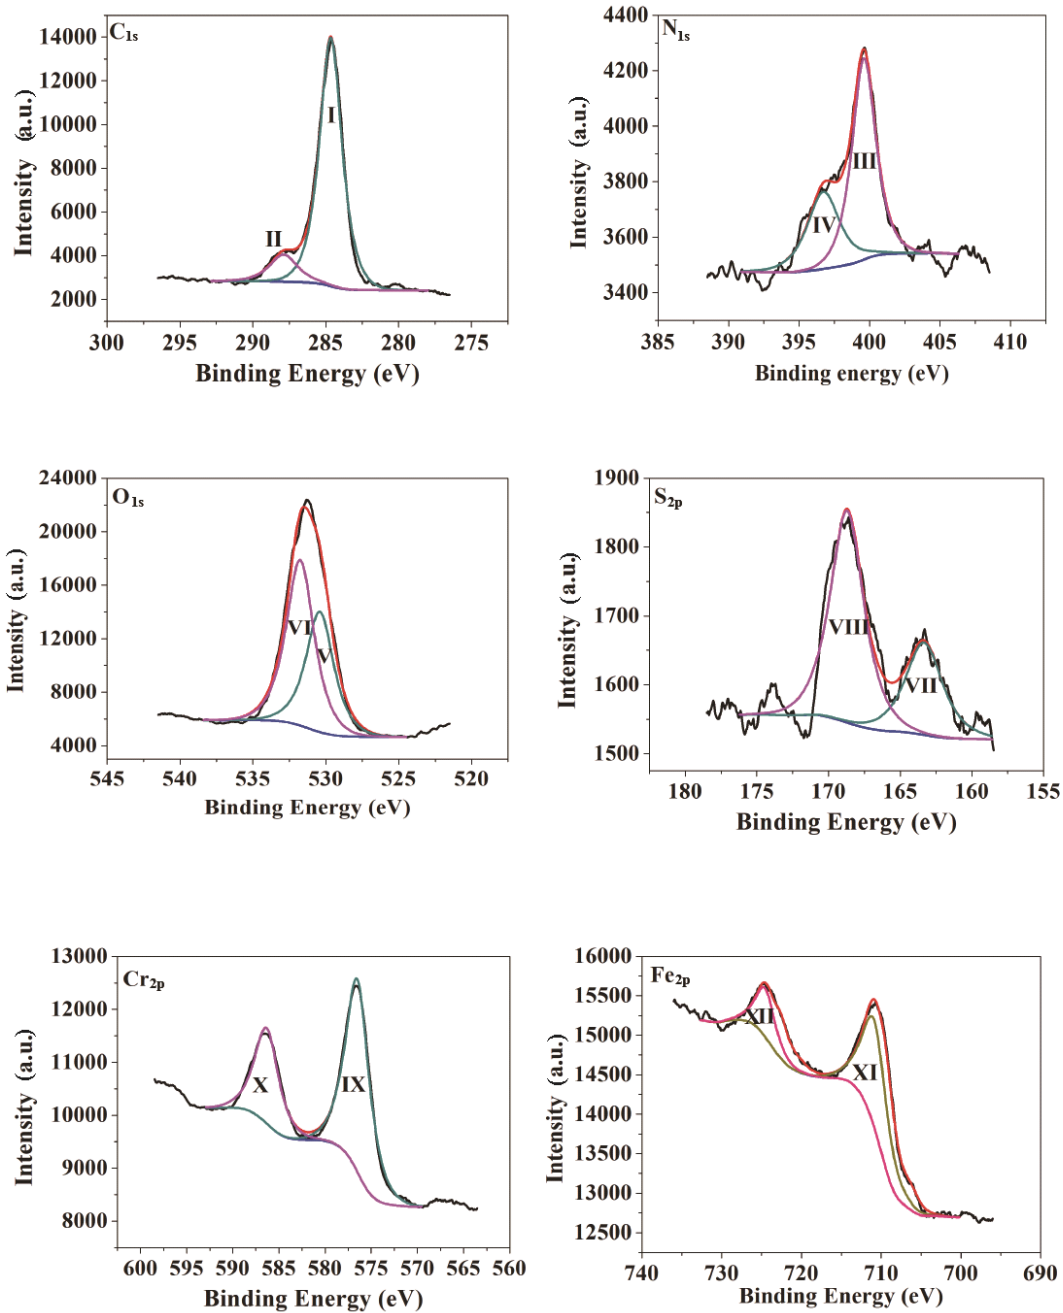

273 Figure 7 shows the EPMA results of the untreated and low temperature nitrided  
 274 samples after immersion corrosion test. It can be seen by comparing Figure 7(b) with  
 275 (a) that oxygen concentration increased significantly in the nitrided layer due to the  
 276 oxygen atoms introduced during the nitriding process. It can be also seen that there is  
 277 an oxygen plateau near the surface, which is overlapped with the grey surface layer  
 278 showed in the top graph of Figure 7(b). This indicates the formation of an oxide layer  
 279 during the salt bath nitriding process. The concentration of nitrogen was increased due  
 280 to the formation of supersaturated austenite, which improves corrosion resistance.  
 281 However, the nitrogen content decreased slightly near the surface, which may be  
 282 caused by the consumption of nitrogen atoms. Combined with the results of XPS  
 283 analysis, it is known that this is due to the reaction of reactive nitrogen in the nitride  
 284 layer with  $H^+$  in the  $H_2S$  solution to form  $NH_4^+$ . For the untreated sample, the iron  
 285 concentration sharply declined on the surface, which means the destruction of the  
 286 passivation film, thus jeopardizing the corrosion resistance of the untreated sample  
 287 leading to the appearance of a large number of corrosion pits on the surface (Fig.2(a)).  
 288

303 Elemental contributions analyses have been performed for carbon, nitrogen,  
 304 oxygen, sulfur, chromium and iron on the H<sub>2</sub>S corrosion tested surface of untreated  
 305 and as-nitrided samples and the results are reported in Figure 8 and Figure 9,  
 306 respectively. The parameters and corresponding atomic contents are detailed in Table  
 307 2.

308 Oxygen (O<sub>1s</sub>) contribution in both untreated and nitrided sample appears as two  
 309 visible although entangling peaks: one for oxides at 530.7 eV and one for hydroxides  
 310 at 531.7 eV.<sup>[25]</sup> XPS analysis results showed that the corrosion products formed on the  
 311 untreated and nitrided samples were approximately the same, mainly Fe<sub>2</sub>O<sub>3</sub>, FeOOH.  
 312 The corrosion products detected by XRD are mainly sulfides, whilst the corrosion  
 313 products detected by XPS are mainly oxides. This is because the detection depth of  
 314 the two techniques is different: the detection depth of XRD is usually in the micron  
 315 range, but the XPS detection is in the nanoscale. Therefore, it can be considered that  
 316 the corrosion product is layered with the oxide content enriched in the outer layer and  
 317 the sulfide content in the inner layer.

318 The characteristic peaks of Cr in nitrided and untreated samples are mainly Cr<sub>2</sub>O<sub>3</sub>  
 319 and a small amount of Cr(OH)<sub>3</sub>. Chromium accumulated in the corrosion product film  
 320 to form a stable amorphous Cr (OH)<sub>3</sub>, which makes the film more stable. At the same

321 time, the corrosion product film mainly containing  $\text{Cr}(\text{OH})_3$  has a certain cation  
322 selective permeability. It can effectively prevent the anion from penetrating the  
323 corrosion product film to the metal surface and reduce the corrosion rate of the  
324 material.<sup>[26]</sup> Since  $\text{Cr}(\text{OH})_3$  is amorphous,<sup>[27]</sup> it does not be detected by XRD.

325 For the  $\text{S}_{2p}$  fit spectrum, 162.2 eV and 163.5 eV can be considered as the peak of  
326  $\text{FeS}_{1.15}$ , which is consistent with the previous analysis. 168.6 eV can be considered as  
327 a characteristic peak of sulfate, such as  $\text{FeSO}_4$ ,  $\text{Fe}_2(\text{SO}_4)_3$ , etc. The presence of  
328 sulfates was not expected to be formed in  $\text{H}_2\text{S}$  electrolyte due to the absence of  
329 oxygen in solution, which could be the consequence of sulfide oxidation during the air  
330 exposition between the end of aging in the  $\text{H}_2\text{S}$  solution and the XPS measurements.  
331 For the nitrated samples, 396.7 eV can be regarded as a characteristic peak of CrN in  
332  $\text{N}_{1s}$  fit spectrum. 399.6 eV can be regarded as a characteristic peak of  $\text{NH}_4^+$ , indicating  
333 that the active nitrogen of the nitrated layer reacts with  $\text{H}^+$  in the  $\text{H}_2\text{S}$  solution,  
334 consumes  $\text{H}^+$ , lowers the pH and protects the metal. The experimental result is  
335 consistent with our previous finding.<sup>[28]</sup>

336 It can be found from Table 2 that after the  $\text{H}_2\text{S}$  corrosion, the S content (13.27 at%)  
337 and Fe content (12.51 at%) of the untreated sample are significantly larger than that of  
338 the nitrated sample (0.3 at% S and 1.93 at% Fe). On the one hand, it is shown that  
339 nitrating can prevent the formation of corrosion products on the surface of the sample,  
340 and on the other hand, it also indicates that the corrosion product is difficult to deposit  
341 on the surface of the sample. The literature indicates that under certain conditions, the  
342 corrosion product film has no protective effect on the substrate and may even lead to  
343 an increase in the corrosion rate.<sup>[29-31]</sup> Since the nitrated layer reduced the production  
344 of corrosion products, further corrosion of the sample can be prevented.

373

Hydrogen permeation occurring on the surface of pipe steel is one of the main risks of steel failure, and the intensity of which can be reflected in the hydrogen permeation current. [32] Zhang et al. investigated the effect of the cathodic current density ( $i$ ) on the permeation of hydrogen through X80 pipeline steels using an electrochemical permeation technique and they provided an equation to describe the relationship between concentration of hydrogen ( $C_0$ ) and cathodic current density ( $i$ ), this equation indicated that  $C_0$  increased with  $i$ . [33] The hydrogen permeation current density curves of different samples are shown in Figure 10. It can be seen that the anodic steady-state current density of untreated samples is significantly greater than that of as-nitrided samples and nitrided & oxide film removed samples. In addition, the untreated sample took a longer period to reach the steady state anode current density than the as-nitrided samples and the nitrided & oxide film removed samples. Figure 11 shows the hydrogen diffusion coefficient  $D_{\text{eff}}$  and hydrogen concentration  $C_0$  for different materials states. The results show that the hydrogen concentration in the untreated sample ( $18.22 \times 10^{-5} \text{ mol}/\text{cm}^2$ ) is significantly higher than that of the as-nitrided sample ( $9.30 \times 10^{-5} \text{ mol}/\text{cm}^2$ ) and the nitrided & oxide film removed samples ( $8.70 \times 10^{-5} \text{ mol}/\text{cm}^2$ ). The reason for this may be that the nitrided layer could trap a large amount of hydrogen, thus resulting in a substantial reduction of hydrogen absorption by the substrate. [34] The hydrogen diffusion coefficient ( $1.79 \times 10^{-8} \text{ cm}^2/\text{s}$ ) of the untreated sample is larger than that of the as-nitrided sample ( $1.64 \times 10^{-8} \text{ cm}^2/\text{s}$ ) and nitride & oxide film removed sample ( $1.51 \times 10^{-8} \text{ cm}^2/\text{s}$ ), indicating the nitrided layer and oxide layer can reduce the diffusion coefficient of hydrogen.

374

## 4. Discussion

#### 375 4.1 The effect of the nitrated layer on hydrogen permeation

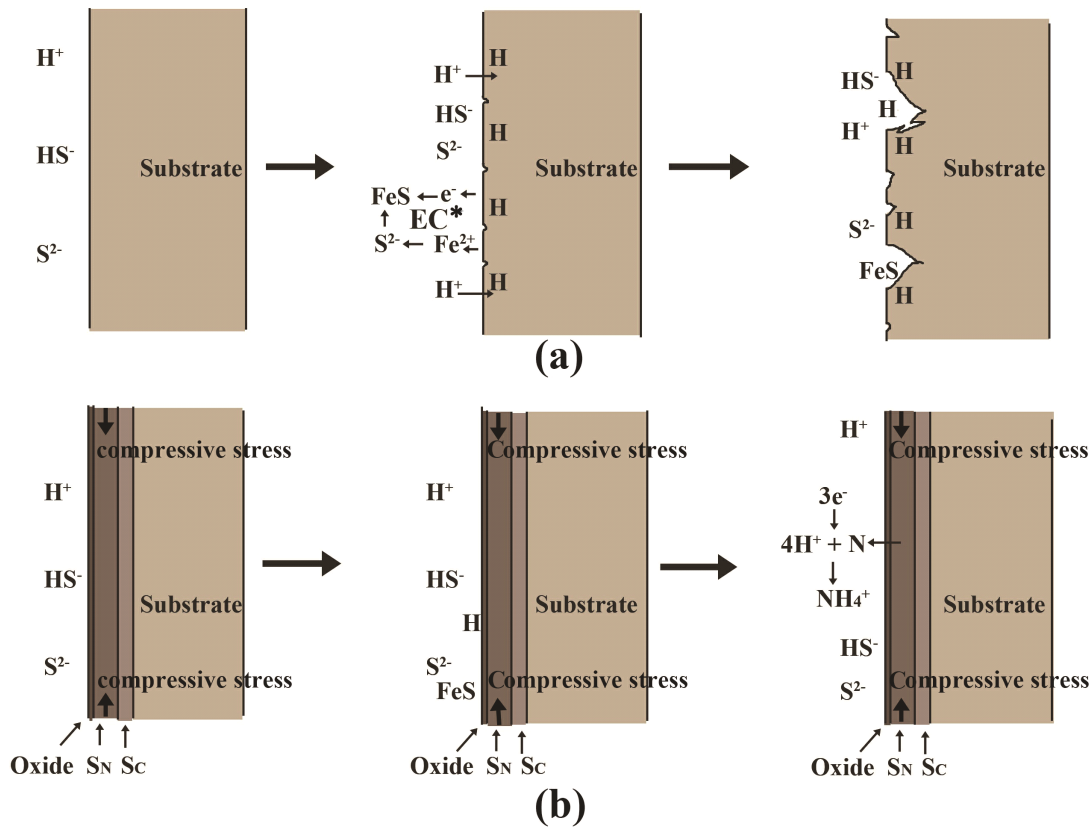

376 When the sample is soaked in the H<sub>2</sub>S containing solution for a long time, H<sub>2</sub>S  
377 reacts with the surface of the steel to produce hydrogen, which then enters the steel  
378 matrix, building up pressure that leads to embrittlement.<sup>[35]</sup> Research has shown that  
379 supersaturated interstitials cause large lattice expansion while the non-nitrated bulk  
380 material constrains this expansion, causing the nitrated layer to have very high  
381 residual compressive stresses.<sup>[36]</sup> Therefore, the residual compressive stress helps to  
382 relieve the tensile stress caused by the H atoms, thus preventing hydrogen  
383 embrittlement. However, when the sample is in a stress corrosion environment and the  
384 applied tensile stress increases to a certain extent, the residual compressive stress of  
385 the S-phase layer may be cancelled out and hydrogen-induced cracking can occur.<sup>[28]</sup>  
386 From the results of electrochemical hydrogen permeation experiment (Fig.10 and Fig  
387 11), it can be seen that both the nitrated layer and the oxide layer help reduce the  
388 diffusion coefficient of hydrogen and the amount of hydrogen atoms entering the  
389 material, thus shorting the time required for the anode current to reach equilibrium.  
390 The possible reason is that the nitrating layer can trap a large amount of hydrogen,  
391 resulting in a substantial reduction of hydrogen absorption by the substrate,<sup>[34]</sup> as  
392 shown in Figure 11.

393 Research has shown that electrochemical H-charging of pulsed plasma nitrated  
394 austenite resulted in a softening effect within the compound layer (S-phase).<sup>[37]</sup> The  
395 hydrogen in the lattice acts as a solution softening agent and the softening or  
396 hardening effect of the hydrogen is dependent on the nitrogen concentration and the  
397 dislocation density of the material. As can be seen from Figure 7, the nitrogen  
398 concentration exceeds 20 at%. When hydrogen ions enter the nitrated layer with a  
399 very high interstitial atom content, it softens and prevents hydrogen embrittlement.

#### 400 4.2 The effect of the nitrating on H<sub>2</sub>S corrosion

401 Figure 12 schematically shows the H<sub>2</sub>S corrosion model for untreated and nitrated  
402 specimens. As shown in Figure 12(a), acidic H<sub>2</sub>S solution hydrolyzes H<sup>+</sup>, HS<sup>-</sup>, S<sup>2-</sup>,  
403 which reacts on the surface of the steel to produce Fe<sup>2+</sup>. When acidic chemical  
404 corrosion occurs, the inherent protective film on the pipe surface is destroyed, causing  
405 the corrosive medium to enter the interior of the metal crystal and generating  
406 electrochemical corrosion. Electrochemical corrosion forms an etched primary cell.  
407 The anode process is a dissolution reaction of the metal, and the cathode undergoes a  
408 hydrogen depolarization reaction. Anodic sulphide corrosion products deposit on the  
409 metal surface, which is poorly protective and in fact promotes the corrosion of the  
410 stainless steel substrate. Monnot et al. highlighted the role of corrosion products on  
411 the failure mechanism of martensitic stainless steels in sour media.<sup>[38]</sup> Corrosion  
412 product formed under this condition has a high level of porosity and is prone to  
413 spalling due to cracks and defects throughout the amorphous structure. In fact, H<sub>2</sub>S  
414 diffuses on the surface of the etching film and penetrates along the porous structure,  
415 and reacts at the metal/film interface. The metal sulphide is formed to release the  
416 hydrogen previously bound to the sulfur that can be absorbed by the alloy. Corrosion

417 product films therefore correspond to a rich hydrogen reservoir near the metal surface  
 418 that can trigger and maintain hydrogen uptake. The data in Table 2 show that nitriding  
 419 treatment can effectively reduce the generation of corrosion products, thereby  
 420 alleviating hydrogen embrittlement and corrosion.  
 421

Note: \* stands for electrochemical corrosion.

422

**Fig.12** H<sub>2</sub>S corrosion model of (a) untreated sample and (b) nitrided sample

423

424

425 The oxide layer can effectively prevent the corrosion of acidic H<sub>2</sub>S as  
 426 schematically shown in Figure 12(b). Granda—Gutiérrez et al. found that  
 427 post-oxidation following nitriding treatment increased the time to SSC rupture of  
 428 stainless steel by a factor of 10 because the dense oxide film on the surface after the  
 429 treatment significantly improved the resistance to H<sub>2</sub>S corrosion cracking of the  
 430 stainless steel.<sup>[39]</sup> This is partially because the nitride layer reduced the generation of  
 431 corrosion products (Table 2) and partially because it also prevented hydrogen atoms  
 432 (Fig.11) from entering the substrate, thereby preventing electrochemical corrosion.

433

434 Nitrogen can effectively improve the local corrosion resistance of stainless steel,<sup>[40]</sup>  
 435 and some hypotheses have been put forward to explain this behavior: (1) high  
 436 concentration of nitrogen atoms on the surface of stainless steel stabilizes passive film  
 437 and inhibits dissolution;<sup>[41-43]</sup> (2) formation of NO<sub>3</sub><sup>-</sup> (nitrate) ions leads to increased  
 438 pitting resistance;<sup>[44]</sup> (3) stabilization effect of nitrogen on austenite.<sup>[45]</sup> For the  
 nitrided samples produced in this research, there are a large amount of active nitrogen

439 atoms in the surface of the sample after low temperature nitriding due to the high  
440 level of chromium, nickel, molybdenum in the matrix material . The fitted spectra of  
441 N1s from the nitriding samples after being soaked in H<sub>2</sub>S solution are shown in Figure  
442 9. H<sup>+</sup> reacts with the nitrogen atom via the reaction:  $N + 4H^+ = NH_4^+$ . This consumed  
443 the H<sup>+</sup> in the solution prevented the pH of the metal surface from decreasing, and  
444 thereby increased the corrosion resistance of the alloy, which is consistent with the  
445 EPMA results in Figure7. At the same time, the active nitrogen atoms can accelerate  
446 the formation of passivation film and affect the repassivation kinetics, so that the  
447 passivation film can grow stably and increase the density of the passivation film.<sup>[46]</sup>

## 448 **5. Conclusions**

449 Low-temperature liquid nitrided samples have better corrosion resistance than  
450 untreated samples in H<sub>2</sub>S environment. The corrosion rate of the untreated sample is  
451 about 3.6 times that of the nitriding sample; clear corrosion pits can be observed on  
452 the surface of the untreated sample, while the treated sample surface remains almost  
453 intact. Due to the presence of oxide layers, despite precipitation of CrN in the  
454 nitriding layer, the corrosion resistance of the sample after the nitriding treatment in  
455 the H<sub>2</sub>S environment is still significantly improved by the treatment.

456 The corrosion products are mainly consisted of oxides, hydroxides, and sulfates.  
457 The nitrided layer reduces the production of corrosion products; further corrosion of  
458 the sample is thus prevented. Both oxide layer and nitrided layer can reduce the  
459 diffusion coefficient of hydrogen and the amount of hydrogen atoms entering the  
460 material, which is beneficial to improving the resistance to hydrogen embrittlement.  
461 Nitriding layer is supersaturated with active nitrogen atoms, which combine with H<sup>+</sup>  
462 to avoid surface pH reduction, thus decelerating H<sub>2</sub>S corrosion.

**Fig.4** Corrosion rate after H<sub>2</sub>S corrosion for 720h

543

544 **Fig.5** XRD patterns for different samples: (a) nitrided sample after corrosion test, (b)  
545 untreated sample after corrosion test, (c) as-nitrided sample and (d) untreated sample  
546 before corrosion test

547 **Fig. 6** XRD patterns as a function of the depth below the original nitrided surface  
548 (after mechanical material removal).

549 **Fig.7** EPMA results of untreated (a) and nitrided samples (b) after immersion  
550 corrosion test in Solution A for 720h

**Fig.8** High resolution XPS spectra of untreated samples after H<sub>2</sub>S corrosion: C1s, O1s,  
S2p, Cr2p, Fe2p.

**Fig.9** High resolution XPS spectra of nitrided samples after H<sub>2</sub>S corrosion: C1s, N1s,  
O1s, S2p , Cr2p , Fe2p .

551 **Fig.10** Hydrogen permeation current density curves of samples under different  
552 conditions.

**Fig.11** Diffusion coefficients and hydrogen atom concentrations curve of the  
sample under different conditions.

**Fig.12** H<sub>2</sub>S corrosion model of (a) untreated sample and (b) nitrided sample

**Table 1** Chemical composition of AISI 304 stainless steel (mass%)

**Table 2** Binding energy and specification for the elements by XPS analysis of nitrided  
and untreated samples after H<sub>2</sub>S corrosion
