**The anatomically preserved tri-pinnate frond *Rothwellopteris*  
*pecopteroides* gen. et sp. nov. from the latest Permian of South China:  
timing the stem to crown group transition in Marattiales**

Xiao-Yuan He, <sup>\*</sup>1 Shi-Jun Wang, <sup>†</sup> Jun Wang, <sup>‡</sup> and Jason Hilton <sup>§</sup>

<sup>\*</sup>Institute of Deep Time Terrestrial Ecology, Yunnan University, Kunming, China; <sup>†</sup>Institute of Botany, Chinese Academy of Sciences, Beijing, 10093 PR China; <sup>‡</sup>State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, P. R. China; <sup>§</sup>School of Geography, Earth and Environmental Sciences, University of Birmingham, Edgbaston, Birmingham, B15 2TT, UK.

*Premise of research.* Fern fronds are common in Late Paleozoic and Mesozoic strata. Large, tri- or multi- pinnate fronds are mainly preserved as impression-compressions while anatomically preserved specimens are typically smaller and comprise dispersed petioles, rachides, ultimate pinna or pinnules. Here we describe a large, anatomically preserved tri-pinnate frond from the latest Permian of SW China that provides the first detailed histological information on a Cathaysian marattialean with pinnule morphology of the cosmopolitan Carboniferous-Permian pecopteroid type, but with different frond anatomy.

*Methodology.* Specimens were prepared by the cellulose acetate peel technique and studied by light

23 microscopy.

24

25 *Pivotal results.* The tri-pinnate frond has a main rachis and primary pinnae rachis with many (> 70)  
26 small vascular bundles arranged in cycles, and abundant tanniferous cells. Pinnules are small and  
27 their bases are entirely attached to the ultimate rachis. Abundant vascular bundles in its rachises are  
28 distinct from previously recognized marattialean genera justifying to the establishment of  
29 *Rothwellopteris pecopteroides* gen. et sp. nov. Comparison of pinnule morphology with  
30 compression/impression fossils demonstrates the specimen to be an anatomically preserved  
31 equivalent of *Pecopteris marginata* Li et al. 1974.

32

33 *Conclusions.* *R. pecopteroides* displays a novel combination of marattialean characters from the  
34 extinct Paleozoic family Psaroniaceae and the extant family Marattiaceae. Its frond morphology  
35 resembles Psaroniaceae including *Psaronius*, but differs from extant Marattiaceae that are  
36 mono-pinnate, palmate or as in *Angiopteris* bi-pinnate, and have large pinnules with contracted bases.  
37 By contrast, its anatomy with abundant vascular bundles is similar to Marattiaceae, especially  
38 *Angiopteris*, but is distinct from members of the Psaroniaceae in which the rachis possesses one or  
39 two tangentially elongate vascular bundles. *P. marginata* shows that by the latest Permian Marattiales  
40 had already evolved frond anatomy typical of extant genera, demonstrating that the stem group to  
41 crown group transition commenced prior to the Triassic.

42

43 *Keywords:* Eusporangiate fern, Marattiales, Psaroniaceae, Marattiaceae, evolution, volcaniclastic tuff,  
44 Xuanwei Formation, stem group, crown group

## Introduction

Marattiales are a clade of living eusporangiate ferns that have an extensive fossil record going back into the early Pennsylvanian approximately 320 million years ago (e.g., DiMichele and Phillips, 1977; Liu et al. 2000; Rothwell et al. 2018). During the late Paleozoic, marattialean ferns were widely distributed in the Euramerican (Morgan 1959; Mickle 1984; Millay 1997; Taylor et al. 2009), Gondwanan (Herbst 1986, 1987, 1992, 1999) and Cathaysian floras (Ogura 1972a; Hill et al. 1985; Gu et Zhi 1974; Li et al. 1995). In these floras fronds and pinnae are relatively commonly, with most preserved as impression/compression fossils that can be identified and classified based on the morphological characters including pinnule shape, size and venation. By contrast, anatomically preserved (permineralized) marattialean leaves mainly represent isolated rachises or terminal pinna that are identified and classified based on the vasculature of rachides (Morgan and Delevoryas 1952a, b; Stidd 1971). In exceptional cases, morphological features of marattialean leaves can also be observed in permineralized specimens, such as *Compsopteris ellipticum* Chang ex Yang et Chen (see Guo et al. 1992). Such fossils, preserved with morphological and anatomical characters, are key to associate impression/compression taxa with permineralized fossils in order to reveal the relationships between them. This is important to the development of whole-plant concepts from fragmentary fossil assemblages (e.g., Rothwell 1999; Bateman and Hilton 2009).

In the late Paleozoic Cathaysian flora, marattialean ferns flourished until the late Permian in eastern Yunnan and western Guizhou provinces in SW China where they constitute an important component in latest Permian floras (Zhao et al. 1980). From this region Marattiales are abundant as

67 vegetative and fertile fronds as well as pinnae preserved as impression-compression fossils (Tian and  
68 Zhang 1980; Zhao et al. 1980; Liu et al. 2000, 2001) and permineralizations (Guo et al. 1992; Hilton  
69 et al. 2004; He et al. 2006). In addition, numerous permineralized marattialean trunks with thick root  
70 mantles have also been found in this region (e.g., Sze 1942, 1947; Yang 1986; Tian et al. 1992; Li et  
71 al. 1995; He et al. 2008, 2010, 2013; D’Rozario et al. 2012). Here from the latest Permian of  
72 Guizhou Province in SW China we report a new kind of marattialean frond preserved with both  
73 morphology and anatomy that has three orders of rachises and attached vegetative pinnules. Based  
74 on its preserved morphological characters, the frond is considered to be the anatomically-preserved  
75 equivalent of *Pecopteris marginata* Li et al. 1974 which was erected based on  
76 impression/compression fossils (Li et al. in Gu et Zhi 1974).

## 77

## 78 **Material and methods**

79 The permineralized marattialean frond reported in this paper was found embedded in a large  
80 rock block (number YNUPB11001) collected from mine spoil from the Xuanwei Formation  
81 (Lopingian Epoch, late Permian period) in Panxian mining district of western Guizhou Province, SW  
82 China. The rock is a volcanic tuff that is white-grey colored but on its surface has weathered to a  
83 yellow-grey color.

84 A diverse fossil plant assemblage has been previously been reported from the Xuanwei  
85 Formation in the Panxian mining district including impression/compression and permineralized  
86 specimens. Impression/compression fossils were primarily described by Zhao et al. (1980). The  
87 assemblage includes the lycopsids *Lepidodendron acutangulum* (Halle), *L. lepidophloides* Yao,  
88 *Stigmaria ficoides* (Sternb.), the sphenopsids *Sphenophyllum koboense* Kobatake, *Sph.*

89 *sino-coreanum* Yabe, *Paracalamites stenocostatus* Li et al., *Annularia pingloensis* (Sze), *A. shirakii*  
 90 Kawasaki, *Lobatannularia cathaysiana* Yao, *L. lingulata* (Halle). *L. multifolia* Kon'no et Asama,  
 91 *Schizoneura brevifolia* Yao, *Sch. manchuriensis* Kon'no, and the noeggerathialeans *Plagiozamites*  
 92 *oblongifolius* Halle, *Discinities* cf. *orientalis* Li et al. Fern and seed fern foliage includes *Chansitheca*  
 93 *kidstonii* Halle, *Sphenopteris tenuis* Schenk, *Pecopteris echinata* Li et al., *P. fuyuanensis* Zhang, *P.*  
 94 (*Asterotheca*) *guizhouensis* Zhang, *P. lingulata* Zhang, *P. marginata* Li et al., *P. sahnii* Hsu, *Rajahia*  
 95 *guizhouensis* Zhang, *R. mirabilis* (Li et al.) Zhang, *R. rigida* (Yabe et Oishi) Zhang, *Fasciapteris*  
 96 (*Ptychocarpus*) *densata* Li et al., *F. hallei* (Kawasaki), *F. stena* Li et al., *Cladophlebis ozakii* Yabe et  
 97 Oishi, *Cl. permica* Lee et Wang, *Cl. parapermica* Zhang, *Neuropteridium coreanicum* Koiwai, *N.*  
 98 *guizhouense* Zhang, *Compsopteris imparis* Li et al., *C. contracta* Li et al., *C. punctinervis* Mo,  
 99 *Gigantonoclea guizhouensis* Li et al., *G. hallei* (Asama), *G. largrelii* (Halle), *G. plumosa* Mo,  
 100 *Gigantopteris dictyophylloides* Li et al., *Taeniopteris* ? *rarinervis* Zhao, *T. crassinervis* Mo,  
 101 *Abrotopteris guizhouensis* (Li et al.) Mo, *Prionophyllopteris spiniformis* Mo. Cycads present in the  
 102 flora are represented by *Pterophyllum eratum* Li et al. and Ginkgoales by *Rhipidopsis pani* Chow, *R.*  
 103 cf. *ginkgoides* Schmalh. and *R. lobulata* Mo, while conifers include *Ullmannia* cf. *bronnii* Goeppert  
 104 and *U.* sp. Permineralized fossils includes the sphenopsid *Calamostachys* sp. (Hilton et al., 2004), the  
 105 marattialean ferns *Compsopteris elliptica* Chang ex Yang et Chen (Guo et al., 1992), *Eoangiopteris*  
 106 sp. (Hilton et al., 2004), *Psaronius laowujiensis* He et al. (He et al., 2010), *P. panxianensis* He et al.  
 107 (He et al., 2008), *P. wangii* Tian et al. (Tian et al., 1992), *P. xuii* He et al. (He et al., 2013). Filicalean  
 108 ferns are rare and limited to *Anachoropteris* sp. (Hilton et al., 2004). Noeggerathialeans include  
 109 pseudo-strobili of *Dorsalistachya quadrisegmentorum* Wang et Spencer (Wang et al., 2017) and  
 110 associated foliage of *Plagiozamites oblongifolius* Halle (Guo et al., 1990). Seed ferns are represented

111 by *Callistophyton boysetii* (Renault) Rothwell (Seyfullah and Hilton, 2011) and ovules of  
112 *Cardiocarpus huopuensis* Wang et al. (Wang et al., 2006), *Muricosperma guizhouensis* Seyfullah et  
113 al. (Seyfullah et al., 2010). Anatomically preserved gigantopterids include *Gigantonoclea*  
114 *guizhouensis* Li et al. (Li et al., 1994), *Aculeovinea yunguiensis* Li et Taylor (Li and Taylor, 1998),  
115 *Vasovinea tianii* Li et Taylor (Li and Taylor, 1999), while conifers are represented by the wood  
116 *Xuanweioxylon scalariforme* He et al. (He et al., 2013).

117 In the tuff the fossil is permineralized by calcium carbonate, with preservation occurring before  
118 significant decay occurred (Neregato et al. 2016). The frond is large and consists of three orders of  
119 branches. We follow Stidd's definition and name the three orders of branches as frond, primary pinna  
120 and ultimate pinna respectively (Stidd, 1971). Frond consists of a rachis (main rachis) and lateral  
121 appendages, i.e. primary pinnae; primary pinna consists of a rachis (primary pinna rachis) and lateral  
122 appendages, i.e. ultimate pinnae; ultimate pinna consists of a rachis (ultimate pinna rachis) and  
123 pinnules. Main rachis is partly exposed on the surface of the rock (Fig. 1a) and is robust, with a  
124 diameter of up to 3 cm (Fig. 1b); primary pinna rachis has a diameter of more than 1 cm, with both  
125 the main rachis and primary pinna rachis having many small vascular bundles; the ultimate pinna  
126 rachis has 4–5 vascular bundles and bears vegetative pinnules. The large size and attached nature of  
127 the different orders of branching in the fossil infers that it was not subjected to significant  
128 taphonomic transportation and fragmentation prior to its preservation as is typical of other  
129 permineralized fossil plant assemblages from tuffaceous sediments in the Xuanwei Formation (e.g.,  
130 Hilton et al. 2004; Neregato et al. 2016; Wang et al. 2017).

131 The specimen was prepared using the cellulose acetate peel method (Galtier and Phillips 1999),  
132 as outlined by He et al. (2006, 2008, 2010, 2013) and Wang et al. (2017). The rock bearing the

specimen, peels and slides are deposited at the Institute of Deep Time Terrestrial Ecology, Yunnan University.

135

## Systematic Paleobotany

*Order – Marattiales Engler and Prantl, 1902*

*Genus – Rothwellopteris gen. nov.* XY He, SJ Wang, J Wang and J Hilton

139

*Generic diagnosis.* Vegetative frond tri-pinnate, pinnules broadly attached, parallel sided, lingulate with rounded tips, veins twice forked. Main rachis and primary pinna rachis possessing numerous small vascular bundles arranged in layers or concentric cycles. Protoxylem endarch.

143

*Etymology.* The new genus is named in honor of the paleobotanical achievements of Gar W. Rothwell.

146

*Remarks.* The new genus is distinguished from all other genera by its combination of *Pecopteris* pinnule morphology with a tri-pinnate frond with its main rachis and primary pinna rachis having many (> 70) small vascular bundles arranged in cycles.

150

*Species – Rothwellopteris pecopteroides sp. nov.* He XY, Wang SJ, Wang J and Hilton J

152

*Specific diagnosis.* Vegetative frond. A tri-pinnate compound leaf. Rachis robust, main rachis up to 3 cm in diameter and primary pinna rachis up to 1 cm in diameter. Ultimate pinna rachis bears

155 subopposite pinnules, pinnules tongue-shaped or somewhat falcate, with length:width ratio less than  
156 3:1. Lateral margin of pinnules thickened, pinnule base slightly expanding; pinnule midrib thick,  
157 lateral veins forking twice and nearly perpendicular to the pinnules lateral margin. Pinnule margins  
158 slightly downturned. Palisade tissue well developed, vascular bundle sheaths marked by ridges on  
159 abaxial pinnule surface. Surface of the first and second order of rachis undulate. Cell walls of the  
160 epidermis thick. Cortex divided into inner and outer cortex. Outer cortex further divided into inner  
161 and outer zones, outer zone consisting of continuous parenchyma with uniform cell size; inner zone  
162 being continuous or discontinuous sclerenchyma bands. Central part of rachis consisting of ground  
163 tissue and many small vascular bundles or meristeles, arranged in poly-cycles. Abundant tannin cells  
164 in ground tissue. Vascular bundles in the outmost cycle possessing a well-developed sheath with its  
165 thickness greater on the pinna abaxial side than that on the adaxial side. The ultimate pinna rachis  
166 possesses two cycles of vascular bundles, each consisting of four vascular bundles.

167

168 *Etymology.* The new species is named after the distinctive pecopteroid-shape of the attached  
169 pinnules.

170

171 *Remarks.* *Rothwellopteris pecopteris* gen. et sp. nov. is interpreted as being the anatomically  
172 preserved equivalent of the compression/impression species *Pecopteris marginata* Li et al. (1974)  
173 that occurs in the Xuanwei Formation in this region. While its pinnule morphology is assignable to *P.*  
174 *marginata*, the species is placed in a new genus because its main rachis and primary pinna rachis  
175 have the distinctive anatomy of a marattialean fern, and deserve a more complete typification as a  
176 new genus. *Rothwellopteris* fronds combine anatomical features of Marattiaceae (concentric

177 arrangement of meristemes) and the Psaroniaceae (petiolar fiber sheath, some tangentially elongate  
178 vascular bundles, pinnule anatomy). We have not retained the species name from the  
179 impression/compression fossil species *Pecopteris marginata* to avoid confusion and to keep the  
180 fossil-taxa separate; we consider the different species reflect an association between different  
181 preservational media of what may be the same biological species.

182

183 *Holotype*. YNUPB11001

184

185 *Depository*. Institute of Deep Time Terrestrial Ecology, Yunnan University.

186

187 *Locality*. Panxian Mine District, Guizhou Province.

188

189 *Stratigraphy and age*. Xuanwei Formation, Lopingian Epoch, Permian Period.

190

## 191 **Description**

192 The frond is a tri-pinnated compound leaf with a preserved length for the first order rachis (main  
193 rachis) up to 30 cm (Fig. 1*a*), but is apically and distally incomplete thus preserving only the middle  
194 part of the frond. The diameter of the main rachis is nearly the same at both ends (Fig. 1*b–c*) with no  
195 obvious tapering, inferring its entire length pre-fragmentation to have been much longer, thus  
196 constituting a large frond.

197

198 *Rachis anatomy*

199 The surface of the main rachis and primary pinna rachis is typically undulated (Fig. 1*c*, 1*e*; Fig.  
200 2*c*, 2*d*) and anatomically they are nearly the same, comprising a narrow cortex with many small  
201 vascular bundles or meristeles within it (Fig. 1*b*, 1*c*, 1*e*; Fig. 2*c*). Epidermal cells are usually poorly  
202 preserved. Their cell walls seem to be thick and are usually preserved as a thin black homogenous  
203 layer (Fig. 1*d*; Fig. 2*d*, 2*e*). The cortex comprises an outer and inner part, with the outer cortex  
204 further divided into two zones of which the outermost layer consists of continuous parenchyma (Fig.  
205 1*d*, Fig. 2*d*, 2*e*). In the main rachis, the outer zone of the outer cortex has a larger radial width, up to  
206 10 cells or 400–500  $\mu\text{m}$  wide. Parenchymatous cells are nearly isodiametric in cross section with  
207 diameters mainly from 40–60  $\mu\text{m}$ . In the primary pinna rachis, the outer zone of the outer cortex is a  
208 little narrower, 3–6 cells or 200–300  $\mu\text{m}$  wide, and cells are smaller with diameters usually less than  
209 50  $\mu\text{m}$ . The inner zone of the outer cortex is a continuous or discontinuous sclerenchyma band. In the  
210 main rachis the sclerenchyma band is mostly discontinuous and is divided into many alternating  
211 sclerenchyma and parenchyma strands (Fig. 1*b–d*; Fig. 2*d*). Sclerenchyma strands are radially  
212 elongate with radial widths of 600–700  $\mu\text{m}$  and a smaller tangential width (Fig. 1*d*). Parenchyma  
213 strands are connected with the outer zone of the outer cortex. In some parenchyma strands, the cells  
214 are obviously radially elongate. Parenchyma cells of the cortex are all approximately isodiametric in  
215 cross section, with diameters of 20–40  $\mu\text{m}$  and thick cell walls. Secretory cavities are scattered in the  
216 parenchyma and sclerenchyma, and some of them contain dark brown contents. In the primary pinna  
217 rachis, the sclerenchyma band tends to be continuous (Fig. 2*b*, 2*c*) with a smaller radial width,  
218 usually 300–500  $\mu\text{m}$ . The inner cortex is usually poorly preserved and can be found only in some  
219 places (Fig. 2*f*). Cells of the inner cortex are similar in size to those of the outer cortex but have  
220 thinner cell walls. Cells of the outer and inner cortex appear elongate in longitudinal section (Fig.

221 3a).

222       There are many small vascular bundles (or meristeles) in the mid part of the main and second  
223 order rachis. The outermost vascular bundles are arranged in a regular ring (fig. 1e; fig. 2c). Inside  
224 this ring, vascular bundles are arranged somewhat irregularly and not in obvious rings (fig. 3b),  
225 probably due to taphonomic disturbance. The number of vascular bundles is more than 70. Most of  
226 vascular bundles are band-like and centripetally arced (fig. 2c; Fig. 3b–d; fig. 4a), but some are  
227 nearly round in cross section (fig. 3e). The well preserved vascular bundles consist of a xylem strand  
228 and sheath. The xylem strand is 1–2 tracheids thick and protoxylem is endarch, located along the  
229 inner side of the strand (fig. 3c, 3d). Metaxylem tracheids of the main rachis are mainly polygonal in  
230 cross section and with diameters mostly more than 40–50 µm, while those of the primary pinna  
231 rachis are smaller, and typically 30–40 µm in diameter. The vascular bundles of the outermost ring  
232 are different from those of the inner rings; cells of the vascular bundle sheath of the former possess  
233 thicker walls that are dark brown or black colored, while cell walls of the vascular bundle sheath in  
234 the inner rings are thinner and are light colored (compare fig. 3c, 3d with fig. 4a). Phloem and  
235 ground tissues are poorly preserved, but many tannin cells with dark or light colored contents can be  
236 seen (fig. 3c, 3e; fig. 4b). Tracheid walls possess scalariform thickenings (fig. 4b).

237       The cortex of the ultimate pinna rachis is 300–400 µm thick and lacks sclerenchymatous strands  
238 (fig. 4e). It can be roughly divided into two zones. Cells of the outer zone are smaller, 20–30 µm in  
239 diameter and with thick walls, while cells of the inner zone are larger, up to 40–60 µm in diameter  
240 and have thinner walls. There are two rings of vascular bundles in the middle part of the ultimate  
241 pinna, with each ring consisting of four vascular bundles among which the one located at the dorsal  
242 side is longer than the others. Xylem strands are thin, 1–2 tracheids thick, and metaxylem tracheids

243 are only 20–30  $\mu\text{m}$  in diameter. The vascular bundle sheath is one cell thick and consists of cells  
244 slightly smaller than the metaxylem tracheids. These cells possess thicker walls and are dark colored.

245  
246 *Ultimate pinnae and pinnule*

247 The ultimate pinnae are all incompletely preserved with the longest one measuring 5 cm in  
248 length. The width of the ultimate pinna is up to 16–18 mm. Pinnules are tongue-shaped (fig. 5*b*; fig.  
249 6*a*) or somewhat falcate (fig. 4*c*; fig. 5*a*), alternate and oriented perpendicular to the ultimate pinna  
250 rachis. Pinnules are up to 9 mm long and up to 3 mm wide in their middle, with blunt tips and  
251 truncate and slightly expanded bases. The midrib is up to 0.3 mm wide and decurrent on the pinna.  
252 The first lateral vein of the lower side at the base diverges from the decurrent part of the pinnule.  
253 Lateral veins diverge from the midrib at an acute (or lower) angle and divide once, then extend to the  
254 margin and divide once again. Ultimate lateral vein branches are perpendicular to the margin of the  
255 pinnule (fig. 5; fig. 6*b*, 6*c*).

256 The midrib of the pinnule appears sturdy and is raised on the lower surface (fig. 6*d*; fig. 7*a*).  
257 Lamina thickness varies depending on the pinnules. In some pinnules, the lamina is 350–400  $\mu\text{m}$   
258 thick, while in other pinnules the lamina is only 250–300  $\mu\text{m}$  thick. The lateral margin of the pinnule  
259 is thicker and bends or is even involute toward the lower surface (fig. 6*d*; fig. 7*a*). Mesophyll is  
260 differentiated into a palisade and spongy tissue (Fig. 7*b*, 7*c*). Palisade tissue is well developed and its  
261 cells have a length reaching half of the thickness of the lamina with many of them possessing black  
262 or dark brown contents. The vascular bundle of the lateral veins is located within the spongy tissue  
263 and has a diameter of 110–130  $\mu\text{m}$ . Vascular bundle sheaths consists of 1–2 layers of nearly round  
264 cells. On the lower and upper surface of the vascular bundle sheath there is a strand of cells which

connect the epidermis and the vascular bundle sheath. The strand which connects the upper epidermis and the vascular bundle sheath is slender and consists of small, thick-walled cells, while the strand connecting the lower epidermis and the vascular bundle sheath is shorter, thicker, and consists of large thin-walled cells. The vascular bundle sheath appears circular in section and defines a ridge on the abaxial (lower) pinnule surface (Fig. 6d).

## Discussion

### *Comparisons with impression-compression species*

The frond from the Xuanwei Formation is preserved revealing both its morphology and anatomy from which information on its pinnule outline and venation enables comparisons with impression-compression species. In outline pinnules are tongue-shaped or falcate with a blunt tip and a truncate and slightly expanded base. These features conform to the circumscription of the genus *Pecopteris* Brongniart, a genus for specimens preserved as impression/compression fossils. Although most species of *Pecopteris* belong to members of the Marattiales, other species have also been assigned to the Zygopteridales, “filicales” including the Tedelaceae or seed plant (e.g., Stewart and Rothwell, 1993). To date, 10 species of *Pecopteris* have been reported from the Xuanwei Formation in western Guizhou and eastern Yunnan provinces, namely: *P. arcuata* Halle, *P. echinata* Gu et Zhi, *P. elegantula* Zhang, *P. fuyuanensis* Zhang, *P. (Asterotheca) guizhouensis* Zhang, *P. lingulata* Zhang, *P. longifolioides* Zhang, *P. marginata* Gu et Zhi, *P. qingyunensis* Zhang and *P. sahnii* Hsu (Li et al., 1974; Zhao et al., 1980; Tian et Zhang, 1980). Among these species, the present frond is comparable to *Pecopteris marginata* Li et al. (1974) in its pinnule outline and venation pattern. However, the type specimen of *P. marginata* is a bipinnately compound leaf which is distinct from the tri-pinnate

287 leaf of the specimen described here. *P. marginata* has a broad rachis and its primary pinna rachis is  
288 up to 6–7 mm wide. The margin of the pinnule has a narrow thickened band, and the base of the  
289 pinnule is slightly expanded. In *P. marginata* the pinnule midrib is thick, lateral veins fork twice and  
290 are perpendicular to the lateral margin of the pinnule. *Rothwellopteris pecopteroides* also has a thick  
291 rachis (rachis is up to 30 mm wide and the second order of rachis is up to 10 mm wide) and the size  
292 of ultimate pinna and pinnules of the present frond are similar to those of the type specimen of *P.*  
293 *marginata*. The base of the pinnules of *Rothwellopteris* are also slightly expanded and the lateral  
294 margin bends or is involute toward the lower surface, and there is a thickened band at the margin of  
295 the pinnule. In the new genus, the midrib is also prominent and lateral veins mostly forked twice and  
296 are perpendicular to the lateral margin of the pinnule. Differences between the present frond and the  
297 type specimen of *P. marginata* is that the new frond is tri-pinnately compound leaf, while the type  
298 specimen of *P. marginata* is a bi-pinnately compound leaf, but this may be the result of  
299 fragmentation and incomplete preservation in the type specimen of *P. marginata*. Furthermore, the  
300 present frond and the type specimen of *P. marginata* were both collected from the same locality and  
301 same stratigraphic interval making it additionally probable that they belong to the same species, with  
302 the *Rothwellopteris* specimen being a permineralized example of *P. marginata*. The discovery of the  
303 new frond specimen establishes that *P. marginata* is a tri-pinnately compound leaf, and not a  
304 bi-pinnately compound leaf.

#### 306 *Comparison with permineralized fossil and living Marattiales*

307 The discovery of the present frond is important as it presents an opportunity to study the  
308 anatomy of a Cathaysian species of *Pecopteris* for the first time. The rachis of the tri-pinnate frond

309 from the Xuanwei Formation has numerous anatomical features that allow it to be placed within the  
310 Marattiales including (1) the presence of abundant vascular bundles that are roughly arranged in  
311 concentric rings, (2) individual vascular bundles being short, band-like and bend internally, (3)  
312 protoxylem distributed along the innermost side of the vascular bundle, and (4) abundant tannin cells  
313 dispersed throughout the tissues (Ogura 1972b).

314 Existing Paleozoic records of anatomically preserved vegetative marattialean fronds have  
315 mainly been found from in the Euramerican and Cathaysian floras. Those from the Euramerican flora  
316 occur in the Pennsylvanian and Cisuralian (lower Permian) from which petioles and rachises are  
317 placed in the genera *Stewartiopteris* Morgan and Delevoryas and *Stipitopteris* Grand'Eury (Morgan  
318 and Delevoryas 1952a, b; Stidd 1971; Table 1). Those from Cathaysia occur in the Cisuralian and  
319 Lopingian (upper Permian) where anatomically preserved petioles or rachises are also assigned to  
320 *Stewartiopteris* and *Stipitopteris* (Xiang et al. 2008). However, the rachises of the present frond  
321 possess abundant small vascular bundles, which clearly distinguish it from both of these genera that  
322 have only one or two long and continuous vascular bundles (Table 1).

323 *Compsopteris elliptica* was established by Yang and Chen (1979) for impression-compression  
324 fossils of mono-pinnate compound marattialean leaves from the Longtan Formation in Guangdong  
325 Province that they considered to most likely represent the frond of a seed fern. Anatomical  
326 preservation of *C. elliptica* was later identified by Guo et al. (1992) who also assigned a  
327 permineralized rachis from the same Formation to *Compsopteris* sp., considering both to represent  
328 marattialean fronds. While *Stewartiopteris* and *Stipitopteris* each possess only 1–2 tangentially  
329 elongate vascular bundles, both *C. elliptica* and *C. sp.* possess more bundles, at least 4–5 in *C.*  
330 *elliptica* and many more in *C. sp.* (Guo et al. 1992), as does the present frond (Table 1). However, the

331 rachises of *C. elliptica* and *C. sp.* are obviously ventral-dorsal in cross section and vascular bundles  
332 are arranged in regular rings which are depressed at the ventral side (or upper side) and consists of  
333 short vascular bundles, while at the dorsal side (or lower side) the rings consists of much longer  
334 vascular bundles (fig. 7d). Unlike *C. elliptica* and *C. sp.*, rachises of the present frond are not  
335 ventral-dorsal in cross section and are not depressed at the ventral side and the vascular bundles of  
336 the present frond are all short or small throughout the frond (compare fig. 2c and fig. 3b with fig. 7d).  
337 Further differences include *C. elliptica* and *C. sp.* having large cells containing dark colored contents  
338 within the outer zone of cortex, and the thickness of the vascular bundle sheath is large and cells are  
339 arranged more tightly at the inner side than at the outer side where the thickness of vascular bundle  
340 sheath is small and cells are arranged loosely. In the present frond, large cells with dark colored  
341 contents within the outer zone of the cortex are absent, and the thickness of vascular bundle sheath is  
342 large and consists of thicker-walled cells at the outer side, but the thickness of the vascular bundle  
343 sheath is small and consists of thinner-walled cells at the inner side (compare fig. 7e with fig. 7f).  
344 The present species is thus also distinct from *Compsopteris* (Table 1).

345 In certain living marattialean plants, the petiole or main rachis also possess abundant short or  
346 small vascular bundles that are arranged in concentric rings, for example, up to 4–5 rings in  
347 *Angiopteris* (Stidd 1971; Ogura 1972b). In this regard, the anatomy of the present frond is more  
348 comparable to living crown group members of the Marattiales within the family Marattiaceae rather  
349 than to extinct members of the Marattialean stem group placed in the family Psaroniaceae (Rothwell  
350 et al. 2018). Obvious differences between the present frond and extant marattialean plants occur in  
351 terms of their morphology (Table 1). The *Rothwelllopteris* frond is tri-pinnate with small pinnules that  
352 are basally truncate, while fronds in Marattiaceae are mostly mono-pinnate or palmate (only

353 *Angiopteris* is bi-pinnate) and pinnules are large and their base is contracted and petioled (Stidd  
354 1971).

355 As well as being distinct from Paleozoic members of the Marattiales within the Psaroniaceae  
356 based on its anatomy, the new frond is also distinct from living Marattiales based on its frond  
357 morphology, leading us to establish the genus *Rothwellopteris* gen. nov. based on its unique  
358 combination of characters. We consider *Rothwellopteris pecopteroides* to represent the  
359 permineralized equivalent of the compression/impression fossil species *Pecopteris marginatus*. New  
360 anatomical information allows moving *P. marginata* from the genus *Pecopteris* that is restricted to  
361 compression/impression specimens, and recognizes its distinct anatomy that has features of both the  
362 Marattiaceae and Psaroniaceae.

363 We consider that *Rothwellopteris* represents an intermediate between the Paleozoic Psaroniaceae  
364 and the stratigraphically younger Marattiaceae (see Rothwell et al. 2018), constituting a stem group  
365 member of the lineage leading to Marattiaceae. *Rothwellopteris* demonstrates that by the end of the  
366 Permian period the ancestral Psaroniaceae had started to diversify and that the stem to crown group  
367 transition within Marattiales was already underway.

368 It is known that up to now most of marattialean fronds with *Pecopteris*-type pinnules were  
369 produced by the *Psaronius* Cotta plant, a marattialean tree fern that was common during the  
370 Pennsylvanian and Permian periods and possessed petioles and rachises assignable to either  
371 *Stewartiopteris* or *Stipitopteris* (e.g., Stidd 1971). The discovery of the present frond enriches the  
372 diversity of the petiole and rachis of marattialean plants with *Pecopteris*-type pinnules.

373 *Rothwellopteris* in demonstrating the first anatomical preservation of a pecopterid marattialean frond  
374 from China shows that at least some Cathaysian species were distinct from those from Euramerica,

and presumably were not produced by the *Psaronius* plant. However, to date no whole-plant species of Cathaysian marattialean fern has been reconstructed from stems or fertile foliage to further assess the organization of the Cathaysian members of the Psaroniaceae with pectopterid pinnules.

The co-existence of *Rothwellopteris pecopteroides*, *Compsopteris elliptica* and *Compsopteris* sp. in the Lopingian (upper Permian) flora of eastern Yunnan and western Guizhou shows that the type of petiole and rachis which possess multiple vascular bundles typical of living marattialean plants had diverged from the ancestral marattialean Psaroniaceae by this stratigraphic interval of time. Although the rachis of *R. pecopteroides*, *C. elliptica* and *C.* sp. each possess multiple vascular bundles, they are each different from each other. The vascular bundles of *R. pecopteroides* are smaller and more numerous, being closer to living marattialean plants than the other species, but in terms of its morphology, it has tri-pinnate compound leaves and its pinnules are small and have a truncated base, characters that may be interpreted as more primitive. Although also different from the frond of *Rothwellopteris*, *C. elliptica* and *C.* sp. also appear more primitive than living marattialean plants in the anatomy of the rachis because it can have long vascular bundles. However, in other regards, the morphology of *C. elliptica* and *C.* sp. are closer to living marattialean plants than *Rothwellopteris* because it has a mono-pinnate compound leaf, its pinnules are large and their base is contracted and petioled. What is now required to further assess the systematic and phylogenetic relationships of *Rothwellopteris* is the development of a whole-plant concept, associating fertile organs and trunks to the same plant species. Such research is currently in progress.

Slide YH-0223. *b*, Paradermal section through two slightly falcate pinnules, showing the venation. Scale bar = 1 mm. Slide YH-0222. *c*, Paradermal section through the lower lobe of a pinnule, showing lateral veins. Scale bar = 0.5 mm. Slide YH-0225. *d*, Cross section through a pinnule, showing midrib (Mr) and thickened lateral margin (arrow). Scale bar = 0.5 mm. Slide YH-0230.

**Fig. 7.** *a*, Cross section through a pinnule showing thick midrib, U-shaped vascular bundle, thickened lateral margin (arrows) and possible hydathodes. Scale bar = 0.5 mm. Slide YH-0230. *b–c*, Part of a cross section through a pinnule, showing palisade tissue, spongy tissue and veins. Scale bars = 0.5 mm. Slides YH-0230, YH-0228. *d*, Cross section of *Compsopteris elliptica* rachis showing tangentially elongate vascular bundles near the dorsal surface. Scale bar = 1 mm. Slide WP2-0193. *e*, Enlargement of specimen in Fig. 7*d*, showing large cells with brown content (arrows) in the outer zone of the outer cortex (OZ); note the thick inner vascular bundle sheath (1), thin outer vascular bundle sheath (2), xylem strand (XS). Scale bar = 200 µm. *f*, Cross section of a second order rachis of *Rothwelllopteris pecopteroides*, with no large cells with brown content in outer zone (OZ) of the outer cortex. The inner vascular bundle sheath (1) is thin and the outer vascular bundle sheath (2) is slightly thicker. Scale bar = 200 µm. Slide YH-0229.

572

	<i>Rothwellopteris</i>	<i>Compsopteris elliptica</i>	<i>Compsopteris</i> sp.	<i>Stewartiopteris</i>	<i>Stipitopteris</i>	<i>Angiopteris</i>
Number of vascular bundles	Numerous	Numerous	Numerous	One	Two	Numerous
Frond morphology	Tri-pinnate	Mono-pinnate	Unknown	At least tri-pinnate	At least tri-pinnate	Bi-pinnate
Pinnule	Broad attachment	<i>Narrow attachment</i>	Unknown	Broad attachment	Broad attachment	<i>Narrow attachment</i>
