45 CONTRIBUTION

What does this work add to what is already known? 46

Antenatal treatment for TAPS differs considerably amongst fetal therapy centers. Perinatal mortality 47

48 is comparable for all treatment groups. Severe neonatal morbidity was significantly higher in cases

49 treated with IUT (± PET) or delivery. Prolonging pregnancy was best achieved in expectant 50 management, laser surgery and selective feticide.

51

52 What are the clinical implications of this work?

- There is no international consensus on the best treatment for TAPS. Treatment groups differed greatly 53
- 54 at baseline, hampering reliability and generalizability of results. To improve outcome for TAPS, a
- 55 randomized controlled trial investigating the best treatment option is urgently needed.

56 **KEYWORDS**

60 The authors report to have no financial nor commercial conflict of interest.

61

62 Abstract

63 **Objective:** to investigate antenatal management and outcome in a large international cohort of 64 spontaneous and post-laser twin anemia polycythemia sequence (TAPS).

Methods: Data of monochorionic twins diagnosed antenatally with TAPS collected in the TAPS Registry between 2014-2019 were included in this study. Antenatal diagnosis of TAPS was based on middle cerebral artery peak systolic velocity (MCA-PSV) > 1.5 Multiples of the Median (MoM) in the TAPS donor and < 1.0 MoM in the TAPS recipient. Cases were assigned to the management groups based on the first treatment that was received. The primary outcome included perinatal mortality and severe neonatal morbidity. The secondary outcome was diagnosis-to-birth interval.

71 Results: In total, 370 TAPS cases were antenatally diagnosed and managed either with expectant 72 management in 31% (113/370), laser surgery in 30% (110/370), intrauterine transfusion (IUT) (with or 73 without partial exchange transfusion (PET)) in 19% (70/370), delivery in 12% (43/370), selective 74 feticide in 8% (30/370) or termination of pregnancy in 1% (4/370). Perinatal mortality occurred in 17% (37/225) of the expectant group, in 18% (38/215) of the laser group, in 18% (25/140) in the IUT (± PET) 75 76 group, in 11% (9/86) in the delivery group and in 7% (2/30) of the co-twins in the selective-feticide 77 group (p = 0.177). Severe neonatal morbidity was 49% (41/84) in delivery, 46% (56/122) in IUT (± PET), 78 31% (60/193) in expectant management, 31% (57/182) in laser surgery and 25% (7/28) in selective 79 feticide (p = 0.027). Median diagnosis-to-birth interval was longest after selective feticide (10.5 weeks; 80 IQR: 4.2-14.9), followed by laser surgery (9.7 weeks, IQR: 6.6-12.7), expectant management (7.8 81 weeks; IQR: 3.8-14.4), IUT (± PET) (4.0 weeks, IQR: 2.0-6.9 weeks) and delivery (0.3 weeks, IQR: 0.0-82 0.5), p < 0.001. Treatment for TAPS varied greatly within and between the 17 fetal therapy centers. 83

Conclusions: Antenatal treatment for TAPS differs considerably amongst fetal therapy centers.
 Perinatal mortality and morbidity were high in all management groups. Prolonging pregnancy was best
 achieved in expectant management, laser surgery and selective feticide.

93 Introduction

Twin anemia polycythemia sequence (TAPS) occurs as the result of chronic unbalanced feto-fetal transfusion through minuscule placental anastomoses in monochorionic twins, leading to anemia in the donor and polycythemia in the recipient¹. Unlike twin-twin transfusion syndrome (TTTS), TAPS develops in the absence of twin oligohydramnios-polyhydramnios sequence (TOPS). TAPS can occur spontaneously in 3-5% of monochorionic twins, or can arise in 2-16% after incomplete laser surgery for TTTS due to the presence of minuscule residual anastomoses^{2, 3}.

100 TAPS is a relatively new disease, with its first description originating from 2006⁴. Since then, knowledge 101 of TAPS has greatly increased and insights into pathophysiology, diagnosis and outcome have gradually been established⁵. However, the best antenatal management option for TAPS is still 102 103 unknown. Options include expectant management, preterm delivery, intrauterine transfusion (IUT) in 104 the donor with or without partial exchange transfusion (PET) in the recipient, fetoscopic laser surgery 105 of the placental vascular anastomoses and selective feticide. Since TAPS is associated with high rates 106 of adverse short- and long-term outcome, it is crucial to investigate which management strategy provides TAPS twins the best outcome⁶⁻⁸. Unfortunately, due to the low incidence of the condition, 107 108 studies are limited to small numbers, hampering generalizability of results and demanding extreme 109 caution when comparing the outcomes. To generate more substantiated knowledge on the effects of 110 management strategies for TAPS twins, we set up the TAPS Registry, an international collaboration 111 aimed at collecting data on diagnosis, management and outcome in TAPS.

The aim of the current study is to investigate perinatal outcome of different antenatal management
 strategies and to report the antenatal management choices for TAPS in various fetal therapy centers
 across the world.

115 Methods

116 *Registry*

117 The TAPS Registry (<u>www.tapsregistry.org</u>) was established in 2014 as a web-based registry for 118 anonymous data collection. Fetal therapy centers across the world were invited to participate. 119 Participating centers were supplied with personal credentials to enter data of their TAPS cases into 120 the online registry. Between 2014 and 2019, a total of 17 centers contributed to data collection (see 121 list in Appendix 1).

122 Inclusion criteria

Women were eligible for the study if they were pregnant with monochorionic twins diagnosed with spontaneous or post-laser TAPS. The diagnosis for TAPS was based on a MCA-PSV discrepancy, with an increased MCA-PSV value (>1.5 Multiples of the Median (MoM)) in the TAPS donor combined with a decreased MCA-PSV value (<1.0 MoM) in the TAPS recipient, in absence of TOPS⁹. Cases were excluded if they only had a postnatal diagnosis of TAPS (and were missed antentally) and/or if they were diagnosed with post-laser TAPS within one week after laser for TTTS, unless TAPS was ongoing after one week and/or if they were first diagnosed with TAPS at stage 5. Of note, the outcome from postnatally diagnosed cases are presented in two other studies investigating outcome in spontaneous and post-laser TAPS separately^{10, 11}.

132 Collected information

133 Data on maternal characteristics, diagnosis, management, delivery, placental injection studies, and 134 perinatal outcome were collected. The following information was retrieved from local medical 135 records: gravidity, parity, location of the placenta, moment of diagnosis (ante- or postnatal), 136 gestational age (GA) at diagnosis and TAPS stage at diagnosis. For antenatal management for TAPS, 137 the type of management was recorded: expectant management, preterm delivery, IUT (± PET), 138 fetoscopic laser surgery, selective feticide or termination of pregnancy (TOP). For each management 139 decision the GA and TAPS stage were noted, as well as the indication. The severity of antenatal TAPS 140 was determined according to the previously published staging system by Slaghekke et al.¹². For 141 delivery, the following parameters were retrieved: type of delivery (spontaneous or planned), mode 142 of delivery (vaginal or cesarean) and type of cesarean (elective or emergency). Based on placental 143 color dye examination, the type, size and number of placental anastomoses were recorded. Perinatal 144 outcome included: donor/recipient status, hemoglobin and reticulocyte values, treatment with blood 145 transfusion for anemia or partial exchange transfusion for polycythemia on day 1, the presence of 146 severe neonatal morbidities and/or severe cerebral injury and the occurrence of perinatal mortality.

147 Management-group allocation

148 We defined the following antenatal management groups for TAPS: expectant management, delivery 149 (defined as a delivery within 7 days after diagnosis), IUT (± PET), laser surgery and selective feticide. 150 Since TAPS cases can be managed according to different strategies in the same pregnancy, 151 management-group allocation was based on the first treatment that was performed. The following 152 rules were applied to management-group allocation: cases were assigned to the laser, IUT (± PET), or 153 selective-feticide group if that was the first treatment they received within 14 days after diagnosis of TAPS (we allowed a one-week re-examination to confirm the diagnosis of TAPS). If this treatment was 154 155 performed after 14 days, cases were included in the expectant management group. If cases received laser surgery combined with an IUT during the same procedure, they were assigned to the laser group. 156

157 When cases had an incomplete laser surgery and other interventions were needed to manage 158 persisting or recurring TAPS, they were assigned to the laser group.

159 *Characteristics for the population*

160 The following parameters were studied for all management groups: type of TAPS (post-laser or 161 spontaneous), location of the placenta, GA at diagnosis, TAPS stage at diagnosis, preterm premature 162 rupture of the membranes (PPROM), GA at PPROM, type of delivery (spontaneous or planned), mode of delivery (vaginal or cesarean), GA at birth, the presence of TAPS postnatally, treatment for postnatal 163 164 TAPS (defined as a blood transfusion for the donor and/or a partial exchange transfusion for the recipient at birth) and number of survivors per case. The postnatal diagnosis for TAPS was established 165 166 on the presence of an inter-twin hemoglobin difference > 8.0 g/dL combined with least one of the following: a reticulocyte count ratio > 1.7 or the presence of only minuscule vascular anastomoses 167 detected through color dye injection of the placenta^{13, 14}. Furthermore, we studied specific 168 169 management-related characteristics for each management group. For expectant management we 170 investigated spontaneous resolution of TAPS (defined as the absence of TAPS postnatally). For IUT 171 (±PET), the number of interventions, time interval between interventions (in days), and site(s) of transfusion were examined. In cases with multiple IUT (± PET) procedures, the median number of days 172 173 between interventions was used. For laser surgery we examined recurrent/persistent TAPS, the 174 presence of residual anastomoses, and delivery within 24 hours after the procedure. For selective 175 feticide, donor/recipient status of the treated fetus and the reason for selective feticide were 176 evaluated. For expectant management, IUT (± PET), and laser surgery any additional treatment after 177 the initial intervention was recorded.

178 Primary and secondary outcomes

179 The primary outcomes of this study were perinatal mortality and severe neonatal morbidity. 180 Secondary outcome was diagnosis-to-birth interval. Outcomes were compared between expectant management, delivery, IUT (± PET), laser surgery and selective feticide, for the total group, and for 181 182 spontaneous and post-laser TAPS separately. Perinatal mortality was defined as fetal demise or 183 neonatal death within 28 days after birth. In the selective-feticide group, perinatal mortality was only 184 reported for the co-twin. Severe neonatal morbidity was defined as the presence of at least one of the following, diagnosed within 28 days after birth or before discharge to home: respiratory distress 185 186 syndrome requiring mechanical ventilation and surfactant, patent ductus arteriosus requiring treatment, necrotizing enterocolitis \geq stage 2¹⁵, retinopathy of prematurity \geq stage 3¹⁶, amniotic band 187 188 syndrome, ischemic limb injury or severe cerebral injury. Severe cerebral injury was diagnosed in case 189 of one of the following abnormalities was identified on cerebral imaging: intraventricular hemorrhage 190 \geq stage 3^{17} , ventricular dilatation (including post-hemorrhagic ventricular dilatation)¹⁸, cystic 191 periventricular leukomalacia \geq grade 2¹⁹, porencephalic or parenchymal cysts, arterial infarction or 192 other severe cerebral lesions associated with adverse outcome.

193 Statistical analyses were carried out using SPSS version 25.0 (IBM, Armonk, NY, USA). Data are 194 presented as medians and interquartile ranges (IQR) or range (minimum-maximum), or n/N (%), as 195 appropriate. A p-value < 0.05 was considered statistically significant. To compare management 196 groups, the outcome in the expectant-management group was set as the reference value. Continuous 197 data on pregnancy level was compared using the one-way ANOVA with Tukey correction. A Chi-square 198 test was used for categorical data on pregnancy-level. To account for the fact that observations 199 between co-twins are not independent, outcomes on fetal or neonatal level were compared using the 200 Generalized Estimated Equation (GEE) module. As a GEE cannot be carried out when an outcome event 201 does not occur in one of the groups, an adjustment to the data was applied. With this adjustment, an 202 unaffected child was changed into an affected child, for all groups. This correction generates more 203 conservative p-values.

204 Results

205 Of the 422 TAPS cases that were entered in the TAPS Registry, 10% (43/422) was diagnosed postnatally 206 and excluded from the study. From the remaining 379 cases, nine cases were excluded based on post-207 laser TAPS diagnosed within one week after laser for TTTS (n = 8) and antenatal TAPS stage 5 at diagnosis (n =1). A total of 370 cases were included in the study. Information on the cases contributed 208 209 by each fetal therapy are detailed in Appendix 1. Antenatal management consisted of expectant management in 31% (113/370), laser surgery in 30% (110/370), IUT (± PET) in 19% (70/370), delivery 210 211 in 12% (43/370), selective feticide in 8% (30/370) and termination of pregnancy in 1% (4/370). Table 212 1 shows diagnosis-, pregnancy- and delivery-related characteristics for expectant management, laser 213 surgery, IUT (± PET), delivery and selective feticide.

214

215 Expectant management group

The median GA at diagnosis in the expectant management group was 22.6 weeks (IQR: 19.9-27.1, 216 217 range: 15.1-35.1). The median antenatal TAPS stage at diagnosis was 2 (IQR: 1-2). Spontaneous 218 resolution was seen in 16% (18/111)* of cases that were managed expectantly, and occurred after 219 stage 1 in 17% (9/52), stage 2 in 13% (6/45), stage 3 in 20% (2/11) and in stage 4 in 20% (1/5). In 11% 220 (13/113) of cases, an alternative management strategy was performed after 14 days of expectant 221 management. An IUT (± PET) was elected in eight TAPS cases (after 15-97 days from diagnosis), based 222 upon progression of TAPS stage (n = 5), ongoing stage 1 TAPS (n = 2) and initial recovery followed by 223 recurrence of TAPS after 13 weeks (n = 1). In five cases managed expectantly, laser surgery was

performed for progression of TAPS (after 15-38 days from diagnosis). In two cases managed with laser
surgery, a delivery took place within 24 hours after the procedure, resulting in miscarriage (23 weeks)
and premature (28 weeks) birth, with double survival in the latter. In the other three cases, perinatal
survival was seen in 5/6 neonates.

228 Laser surgery group

Laser surgery was performed at a median GA of 22.0 weeks (IQR: 19.5-24.3, range: 16.1-30.1). 229 230 Spontaneous TAPS cases made up the majority of this treatment group (78%; 86/110). In total, 43% (47/110) of the TAPS cases treated with laser surgery had an anterior placenta. Laser surgery was 231 232 combined with an IUT in the same procedure in 11% (12/110) of the cases. In 4% (4/108) of cases 233 treated with laser, a delivery took place within 24 hours after the procedure (at 21, 22, 24 and 28 234 weeks). Recurrent TAPS was seen in 15% (16/106) of the cases treated with laser surgery. Out of the 235 16 cases with recurrent TAPS, one was diagnosed with TAPS only postnatally. The remaining 15 were 236 managed expectantly in 2% (3/110), with IUT (± PET) in 5% (5/110), laser reintervention in 2% (2/110) 237 and selective feticide in 6% (5/110). In the cases managed expectantly, spontaneous resolution of 238 TAPS was seen in one case. In the other two cases neonatal mortality occurred in three of four liveborn 239 infants. In the recurrent-TAPS cases that were managed with IUT (±PET), fetal demise of the donor 240 occurred in two out of the five twins after the first IUT. In both cases the co-twin survived. In the other 241 three cases, two or three IUT (± PET) interventions were performed and all infants survived. Both laser 242 reinterventions for recurrent TAPS were successful resulting in perinatal survival of the twins. Five 243 recurrent TAPS cases were treated with selective feticide; four were performed in the donor twin, one 244 in the recipient twin. In one case, fetal demise of the co-twin occurred. Aside from the recurrent-TAPS 245 cases, a selective feticide was performed in two other cases treated with laser surgery, based on 246 severe cerebral injury in the donor detected after laser intervention. In 9% (6/65) of liveborn twin 247 pairs treated with laser surgery, postnatal TAPS was diagnosed. Placental injection information was 248 available in 32% (36/110) of cases treated with laser surgery. Residual anastomoses, which were always minuscule, were detected in 19% (7/36). All cases with residual anastomoses (100%; 7/7) had 249 250 recurrent TAPS.

251

252 IUT (± PET) group

An IUT (± PET) was performed at a median GA of 26.3 weeks (IQR: 23.6-28.8, range: 18.0-32.1). The median antenatal TAPS stage at diagnosis was 2 (IQR: 1-2). An IUT was combined with PET in the recipient in 21% (15/70). In total, 73% (51/70) of the IUT (± PET) group had one intervention, 13% (9/70) had two, 7% (5/70) had three, 6% (4/70) had four, and 1% (1/70) had six interventions with IUT (± PET). The median time between interventions was 13.0 days (IQR: 8.6-16.8; range: 6.5-21.0). The

- 258 transfusion site was only intravenous in 70% (15/67), only intraperitoneal in 10% (7/67), and combined
- 259 in 19% (13/67). An alternative management strategy was decided in 14% (10/70) of the cases treated
- 260 with IUT (±PET). Three cases were treated with laser surgery, all within one week after the first IUT
- 261 and based on progressive or recurrent TAPS. One laser procedure was complete, the other two were
- 262 incomplete and both had recurrent TAPS. In seven cases treated with IUT (± PET), a selective feticide
- 263 in the TAPS donor was performed based on recurrent or progressive TAPS (n = 5) or severe cerebral
- 264 injury (n = 2).
- 265 Delivery group
- 266 Delivery (within 7 days after diagnosis) took place at a median GA of 31.9 weeks (IQR: 29.1-34.1; 267 range: 26.0-36.0). The median antenatal TAPS stage for cases treated with delivery was 1 (IQR: 1-2). 268 In total, 88% (76/86) had a cesarean section.
- 269 Selective feticide group
- 270 Selective feticide was performed at a median GA of 22.1 weeks (IQR: 19.9-23.2, range: 17.1-24.6).
- Reasons for selective feticide included TAPS (67%; 20/30), or TAPS with co-existing: severe growth 271 272 restriction (10%; 3/30), severe cerebral injury (10%; 3/30), or congenital anomalies (10%; 3/30) In one
- 273 case, selective feticide was performed on request of the parents (3%; 1/30). In 87% (26/30) of the
- 274 group, selective feticide was performed in the TAPS donor.
- 275 *Comparison of outcome between groups*
- 276 Table 2a provides further information on the outcome for each management strategy. The rate of 277 perinatal mortality was comparable for expectant management (17%; 39/225), laser surgery (18%; 278 38/215), IUT (± PET) (18%; 25/140), delivery (11%; 9/86), and selective feticide (7%; 2/30), p = 0.177. 279 Severe neonatal morbidity was significantly higher in twins treated with delivery (49%; 41/84) and IUT 280 (± PET) (46%; 56/122) than in twins managed expectantly (31%; 60/193), treated with laser surgery 281 (31%; 57/182) or selective feticide (25%; 7/28), p = 0.027. Diagnosis-to-birth interval was 7.8 weeks 282 (IQR: 3.8-14.4) in the expectant management group, 9.7 weeks (IQR: 6.6-12.7) after laser surgery and 283 10.5 weeks (IQR: 4.2-14.9) after selective feticide and was significantly shorter in twins treated with 284 delivery (0.3 weeks, IQR: 0.0-0.5) and IUT (± PET) (4.0 weeks, IQR: 2.0-6.9), p < 0.001. The prevalence 285 of postnatal TAPS was comparable for expectant management (74%; 66/89), IUT (± PET) (71%; 36/51), 286 and delivery (84%; 36/43), and significantly lower in twins treated with laser surgery (9%; 6/65), $p < 10^{-10}$ 287 0.001. In table 2b and 2c, outcome for management strategies are presented for spontaneous TAPS 288 and post-laser TAPS separately.
- 289
- 290 Management choices for 17 fetal therapy centers

Figure 1 shows management choices for TAPS amongst 17 fetal therapy centers. Overall, management varied considerably. Some centers, like Leiden, Milan and Brisbane, adopt a more conservative attitude and manage a considerable number of cases expectantly. In contrast, London, Paris, and Houston treat TAPS cases more invasively, with laser treatment or selective feticide. Fetal therapy centers in Hamburg and Barcelona generally refrain from doing in-utero interventions and manage the majority of cases expectantly or with delivery. The remaining centers do not show a remarkable trend or preference in management and apply the different treatment options alternately.

298

299 Discussion

This is the first large international study investigating outcome after antenatal management for TAPS. We found that perinatal mortality and severe neonatal morbidity rates were high in all treatment groups. Management for TAPS varied considerably within and between fetal therapy centers, reflecting the lack of international consensus on the most optimal management strategy. With this study we present new information on treatment for TAPS, thereby providing a more detailed context to management decisions, leading to a more enhanced understanding of TAPS and the clinical implications of each treatment strategy.

307 Perinatal outcome

308 Confirming findings from previous smaller studies²⁰⁻²², we found comparable perinatal mortality rates 309 for all management strategies, for the total cohort as well as for spontaneous and post-laser TAPS 310 separately. Notably, post-laser TAPS twins showed substantially higher rates of perinatal mortality 311 than spontaneous TAPS twins in all management groups, illustrating the impact of preceding TTTS on 312 the outcome of twins with post-laser TAPS. Severe perinatal morbidity rates were high in all groups, 313 but were significantly increased in cases treated with IUT (± PET) or delivery. Notably, twins managed with IUT (± PET) were delivered at a significantly earlier gestation, which is known to have significant 314 impact on short-term outcome^{10, 11}. However, twins that had a delivery were born at a comparable 315 gestation as twins treated with laser, which might suggest that other factors might also play a role. 316 317 Our results show that expectant management, laser surgery and selective feticide generate a 318 prolongation of pregnancy of 7-10 weeks after the diagnosis of TAPS. A prolonged pregnancy after 319 laser surgery compared to expectant management and IUT (± PET) was previously reported by 320 Slaghekke et al.²⁰. Our study shows that TAPS cases treated with IUT (± PET) had a significantly shorter 321 diagnosis-to-birth interval. Although gestation can be prolonged by reintervention with IUT (± PET), 322 the majority of TAPS cases had only one intervention. A possible explanation could be that due to the 323 relatively high GA at diagnosis, caregivers preferred delivery with subsequent postnatal treatment

over continuous exposure of TAPS, as soon as an acceptable gestation was achieved. The shortest
 diagnosis-to-birth interval was seen in the delivery group, in accordance with the management-group
 definition.

327 Optimal treatment?

328 Determining the most optimal treatment option is crucial to improve outcome in TAPS. Laser surgery 329 is the only management option that directly treats the cause of TAPS, and has shown to drastically improve outcome in TTTS²³. However, laser in TAPS is technically more challenging than in TTTS, due 330 331 to the absence of TOPS, which may lead to reduced accessibility and visibility of the placental surface. 332 This can be especially problematic in case of an anterior placenta. To optimize technical conditions, 333 TOPS can be artificially created with amnioinfusion in one sac and amniodrainage of the other, but 334 this requires more needle insertions and might increase chances of PPROM and premature birth. 335 However, we report PPROM in 37% and delivery within 24 hours after laser in 4%, which is comparable 336 to laser for TTTS³. A second technical problem comes with the size of TAPS anastomoses, which are 337 known to be minuscule and might therefore be harder to find during procedure. In line, our data 338 showed that TAPS recurred in 15% of cases treated with laser surgery, which is more than twice as 339 high as the recurrence rate of TTTS after laser³. Moreover, we have shown that residual anastomoses 340 after laser for TAPS always lead to the recurrence of the disease. To prevent residual anastomoses and 341 to ensure coagulation of anastomoses that cannot be visualized, the Solomon technique might be of added value³. Nevertheless, the rate of residual anastomoses in TAPS was comparable to the rate of 342 residual anastomoses in TTTS (both 19%),³ and 43% of lasers were performed in cases with an anterior 343 344 placenta, showing that, despite the practical limitations, laser for TAPS is technically feasible.

345 Although promising in approach, our data show that laser surgery does not seem to improve (nor 346 deteriorate) perinatal outcome when compared to expectant management. However, laser surgery 347 was associated with a high diagnosis-to birth interval, especially in contrast to treatment with IUT (± 348 PET). As prematurity has a profound impact on short- and long-term health in TAPS twins, prolonging pregnancy is of utmost importance to improve outcome ^{6,7,10,11}. Notably, a comparable prolongation 349 350 of pregnancy was achieved with selective feticide and expectant management. However, selective 351 feticide comes with a high price, as parents lose at least one baby and do not have a guarantee of 352 healthy survival for the co-twin. Alternatively, in expectant management, prolonging of pregnancy 353 likely results in continuous exposure to potential detrimental effects of TAPS, as only 16% showed spontaneous resolution. As risk for perinatal mortality and morbidity increases with incrementing 354 antenatal TAPS stage, definitive treatment with laser might be the most optimal intervention to 355 356 improve perinatal outcome for this condition^{24, 25}.

357 One should be extremely cautious with drawing conclusions based on the results of this registry. Due 358 to the retrospective nature of this study, management groups are very likely to be subject to selection 359 bias. As our data have indicated, management groups differed in terms of GA at diagnosis, severity of 360 TAPS, and type of TAPS. Since higher TAPS stages and post-laser TAPS are associated with poorer prognosis, these factors could have significantly influenced perinatal outcome rates^{10, 11}. Moreover, 361 362 long-term outcome was not investigated in this study. Previous studies have shown that the 363 detrimental effects of TAPS are not limited to the perinatal period, but also manifest later in life^{6,7}. 364 Therefore, the true effect of management for TAPS can only be properly investigated when TAPS cases 365 are randomized between treatment groups, when stratification for risk factors is applied, and when 366 long-term consequences are taken into account.

In conclusion, this registry shows that there is an extensive heterogeneity in management for TAPS, both within and amongst fetal therapy centers. To improve outcome in TAPS, and to generate an international consensus on optimal management, a randomized controlled trial (RCT) is urgently needed. Recently, the TAPS trial, an international multicenter open-label RCT comparing laser surgery to standard care (expectant management, IUT (± PET), preterm delivery) has started recruiting patients²⁶.
