Abstract

| 27 | This work demonstrates the effect of tin (Sn) doping on the manufacturing, electrochemical |
|----|---|
| 28 | performance, and carbon deposition in dry biogas-fuelled solid oxide fuel cells (SOFCs). Sn |
| 29 | doping via blending in technique alters the rheology of tape casting slurry and increases the |
| 30 | Ni/ScSZ anode porosity. In contrast to the undoped Ni/ScSZ cells, where open-circuit voltage |
| 31 | (OCV) drops in biogas, Sn-Ni/ScSZ SOFC OCV increases by 3%. The maximum power |
| 32 | densities in biogas are 0.116, 0.211, 0.263, and 0.314 W/cm ² for undoped Ni/ScSZ, undoped |
| 33 | Ni/ScSZ with 3wt% pore former, Sn-Ni/ScSZ and Sn-NiScSZ with 1wt% pore former, |
| 34 | respectively. Sn-Ni/ScSZ reduces the effect of the drop in the maximum power densities by |
| 35 | 26% to 36% with the fuel switch. A 1.28 to 2.24-fold higher amount of carbon is detected on |
| 36 | the Sn-Ni/ScSZ samples despite the better electrochemical performance, which may reflect an |
| 37 | enhanced methane decomposition reaction. |

52 **1 Introduction**

Solid oxide fuel cells (SOFC) are efficient high-temperature fuel cells with ceramic electrolyte 53 that operate between 600°C and 1000°C[1]. Coupled with combined heat and power system 54 (CHP), the SOFC efficiency can reach up to 90%[2,3]. The key distinction between SOFCs 55 and low-temperature fuel cells is that aside from pure hydrogen the former can operate with 56 alternative fuels, including bio-hythane[4,5], ethanol[6–8], kerosene[9], propane [10–12], 57 ammonia[13,14], syngas[15], methane[16–20], and biogas[14,21–26], where CO also serves 58 as a reactant in the electrochemical reactions [14,19,27-29]. This ability is a remarkable 59 60 advantage given the high cost of pure hydrogen required in low-temperature fuel cells although when hydrogen produced from renewable energy [30,31]. Furthermore, methane (natural gas) 61 distribution infrastructure already exists whereas the hydrogen distribution network will need 62 to be built from scratch. 63

64

Biogas from wastewater treatment plant contains 60 to 80% CH₄, 30 to 50% CO₂, and traces 65 of impurities [32,33]. Biogas utilisation as an alternative fuel is significant, as based on 2012 66 data, the global biogas production exceeded 56 billion m³/year with the energy potential of 67 1212 PJ [34] led by European countries. Pairing this abundant and under-utilized fuel with 68 SOFC with higher efficiency would increase the generated electricity while considerably 69 reducing the carbon footprint of energy services. In addition, studies by Johnson et al.[35] and 70 71 Hagen et al.[36] show that the presence of CO₂ (instead of pure methane) in biogas can suppress the effect of sulphur poisoning. 72

73

The conventional strategy for using hydrocarbon fuels is by implementing a separate (external) reforming chamber [37], which induces additional capital and operating costs, and additional effort for supplying the heat to the reforming reactor. The SOFC module is then fed with hydrogen or syn-gas from the reforming chamber to avoid the deteriorating effect of carbon
deposition on the SOFC anode[37,38]. On the hand, integrating the reforming reaction into the
fuel cell itself (internal reforming) allows for internal heat recycling and thus higher efficiency,
but also increases the danger of carbon deposition due to the varying conditions and chemical
composition of the fuel gas along the flow path through the fuel cell.

82

For a SOFC fuelled by hydrogen, only the electrochemical conversion to electricity and heat, 83 with the reaction product water occurs (Eq.1)[14]. For carbon fuelled-SOFC with internal 84 85 reforming, more chemical and electrochemical reactions may occur due to the existence of six species (CH₄, H₂, CO₂, CO, H₂, and C) in the anode side from the feed and the product of 86 different reactions [19,22]. The steam and dry reforming reactions occur internally (Eq. 2a and 87 b, respectively) with hydrogen (H₂) and carbon monoxide (CO) as the products [14,19,22]. 88 Steam reforming reaction (Eq. 2a) may take place even without steam addition on the anode 89 surface from the product of H₂ electrochemical reaction (Eq.1) [14,19]. The dry reforming 90 91 reaction (Eq. 2b) is an overall reaction of two other major reactions: high temperature methane decomposition (Eq. 3) and carbon oxidation by CO₂ (Eq. 4) [19,22]. Methane decomposition 92 (Eq.3) can occur on both anode substrate (AS) and at the anode functional layer (AFL) [19]. 93 From inspection of Eq.3 and Eq.4, it is clear that both part-reactions need to be in balance since 94 a lack of carbon oxidation according to Eq.4 would otherwise lead to excess carbon remaining 95 96 on the catalyst surface, essentially forming a soot cover that will deactivate the catalyst on anode[39]. At SOFC operating temperature, water-gas shift reaction (Eq. 6) (or the reverse 97 reaction) may also accompany the reforming reaction [14,22]. The electrochemical reaction 98 (Eqs. 1 and 7) tend to occur at the anode functional layer (AFL) region, where more triple-99 phase boundary (TPB) areas are found. 100

102
$$H_2 + \frac{1}{2}O_2 \to H_2O$$
 (1)

$$103 \quad CH_4 + H_2 0 \leftrightarrows 3H_2 + CO \tag{2a}$$

$$104 \quad CH_4 + CO_2 \rightleftharpoons 2H_2 + 2CO \tag{2b}$$

105
$$CH_4 \rightleftharpoons C(s) + 2H_2$$
 (3)

$$106 \quad C + CO_2 \rightleftharpoons 2CO \tag{4}$$

$$107 \quad C + H_2 0 \ \Leftrightarrow \mathrm{CO} + H_2 \tag{5}$$

$$108 \quad CO + H_2O \leftrightarrows CO_2 + H_2 \tag{6}$$

109
$$CO + \frac{1}{2}O_2 \to CO_2$$
 (7)

Deposited carbon can be removed with carbon oxidation with CO₂ (Eq. 4) or steam (Eq.5), which will occur via a sufficient supply of the oxygen sources from steam reforming (Eq. 2a), dry reforming (Eq. 2b). Sumi et al.[40,41] and Farrell et al.[8] shows that significantly less carbon in the area within closer proximity to the electrolyte layer, i.e higher carbon oxidation reaction occurred in the TPB area than that on the further position. Hence, it shows that the oxygen ions that diffuse through the electrolyte in fuel cell operation can also be utilised. SOFC are therefore more prone to carbon formation when idling at open circuit voltage (OCV).

118

With conventional SOFC cells, the Ni/YSZ anode performance drastically drops when the system is switched from hydrogen to pure methane or biogas fuels expected due to carbon deposition[24,27,42,43]. Carbon deposition may block the TPB and pores on the anode, leads to total anode deactivation, and further halt the SOFC operation[18]. As carbon oxidation also depends on the catalytic activity of the anode material, extensive work focuses on improving the anode catalytic activity for carbon oxidation.

Although Ni is an excellent catalyst for both electrochemical oxidation reaction and reforming reaction in producing hydrogen and syngas (H₂ and CO)[44–48], Ni also prone to carbon deposition. Hence, Ni-free anode with alternative metal[6,17,49] and perovskites material [50,51] that show better tolerance towards carbon are widely investigated. Still, Ni is widely preferred as the metal catalyst in SOFC anode due to poor catalytic activity in the electrochemical reaction, incompatibility with thermal expansion of other SOFC layers, and low mechanical strength of the alternative materials when compared to Ni[22].

133

134 Another strategy, avoiding the replacement of Ni, is by reducing the affinity of Ni to carbon by replacing the support oxides (YSZ) or by alloying with other metals[39]. Replacing yttria-135 stabilized zirconia (YSZ) with scandia-stabilized zirconia (ScSZ) or gadolinia-doped ceria 136 (GDC) can successfully improve the tolerance of the anode when tested in methane and biogas 137 [40,52,53] due to higher availability of oxygen ions for carbon oxidation. ScSZ with higher 138 conductivity than YSZ displays different types of carbon[40,43] and carbon deposition 139 behaviour[40,54,55] compared with Ni/YSZ cells, which is due to the difference in crystalline 140 structure [40,43]. 141

142

Surface alloying with precious metal such as Pt, Pd, Au, Ru, and Rh[56,57], or base metals, such as Sn, Sm, Co, Fe, Cu, and Ag[24,58,59] can modify Ni in such a way that it preferentially oxidizes C atoms to CO and CO₂ rather than forming C–C bonds[58]. Jiang et al.[24] showed that alloying Ni with Sn achieves the best performance compared with Ag and Cu. Across several works, the electrochemical performance of Sn–Ni/YSZ cells is unchanged or within 5% of drop when the fuel is switched from hydrogen to methane or dry biogas, whereas that of Ni/YSZ cells substantially drops[18,27,60].

Using density functional theory and temperature-programmed reduction with humidified 151 hydrocarbon fuels on Sn-Ni/YSZ, Nikolla et al. [58] suggested that (i) Sn/Ni catalyst has 152 higher efficiency in forming C-O bonds than C-C bonds compared to Ni, which resulted in less 153 solid carbon deposited on the anode, (ii) Higher active sites of Sn/Ni compared to under-154 coordinated Ni active sites, and (iii) Sn/Ni lessen the binding strength of carbon atoms on the 155 anode. In agreement with studies by Nikolla et al.[58], Kan et al.[18] and Farrel et al.[8] shows 156 157 less amount of carbon detected on most of the Sn doped cells with humidified fuel or high oxygen to carbon ratio fuel. Kan et al.[18] shows improved stability with operation up to 137 158 159 hours with Sn-Ni/YSZ cell compared to 27 hours with undoped cells in humidified methane. On the other hand, Singh et al. [42] and Lay et al. [61] reported no significant performance 160 difference and higher amounts of carbon observed on the Sn doped cells compared to the 161 undoped cells with either low steam to carbon ratio. Troskialina et al.[27] and Jiang et al.[60] 162 tested Sn-Ni/YSZ with dry biogas fuel instead of humidified hydrocarbon fuel. All studies 163 [8,27,42] agreed on small amount of Sn (1wt%) as the optimum quantity, in which a higher 164 concentration of Sn decreases the performance due to an increase in polarisation resistance. 165

166

To date, the effect of Sn/Ni alloying has only been tested on Ni/YSZ cells mostly via the surface impregnation method. The metal surface impregnation method introduces several additional steps where the catalyst needs to be repeatedly dispersed on the targeted surface followed by drying and calcination to remove the precursor [27,42]. The work reported here attempted to i) investigate the impact of Sn doping on the electrochemical performance of biogas internal reforming on Ni/ScSZ and the amount of carbon deposited, and ii) test alternative and simpler dopant introduction methods by blending in with the tape casting slurry.

174

176 **2 Experimental**

177 2.1 Materials

The as-received commercial powders used for electrolytes were 10ScCeSZ ((Sc₂O₃)_{0.1-} 178 (CeO₂)_{0.01}–(ZrO₂)_{0.89}); from DKKK with an average particle size of $0.514 \pm 0.053 \mu m$ (d₅₀). 179 For the anode substrate (AS), coarse nickel oxide (NiO) with a particle size of 8.101 ± 0.185 180 μ m (d₅₀) from Novamet and pre-calcined 10ScCeSZ (DKKK) with a particle size of 0.372 ± 181 182 0.001 (d₅₀) were used with a weight ratio of 65:35. Fine as-received NiO (Pi-Kem Ltd.) with an average particle size of $0.637 \pm 0.145 \,\mu\text{m}$ and as-received 10ScCeSZ (DKKK) were mixed 183 184 in the same ratio for the anode functional layer (AFL). SnCl.2H₂O (Sigma Aldrich, UK) was used as the precursor of Sn to produce Sn-doped Ni/ScSZ cells. As-received lanthanum 185 strontium manganese, La0.80Sr0.20MnO3 (LSM, Praxair) with an average particle size of 0.90 186 µm was used for cathode. 187

188

189 2.2 Methodology

190 2.2.1 Sn–Ni/Scsz Cell Fabrication Via Aqueous Tape Casting

Figure 1 shows the two ball-milling mixing steps performed for the full-cell fabrication of the 191 standard Ni/ScSZ cells, as reported in previous work [53]. For Sn-doped cells, SnCl₂.H₂O 192 (1wt% of Sn/Ni) was pre-dispersed with NiO powder by ball milling for 1 h at 120 rpm with 193 water and dispersant. Then, 0wt% and 1wt% pore former were used in this Sn-NiScSZ 194 formulation in accordance with the practicality of the manufacturing method and the targeted 195 porosity of the cells. A high amount of plasticizer and binder was used in leverage to the pore 196 former amount for cells with less pore former, and the 1:1 ratio of binder to plasticizer and 197 solid loading of 55 wt% was maintained. The same formulation with 0wt% and 3wt% pore 198 former was used for undoped Ni/ScSZ cells. The porosity of the reduced anode shown in Table 199 2 was measured via the Archimedes method. 200

| 201 | A reverse or co-casting tape-casting method [53,62,63], with inverted layer application to the |
|-----|---|
| 202 | conventional method was used with an aqueous-based formulation. A thin layer of electrolyte |
| 203 | was cast first, followed by AFL and AS with drying periods in between. Tape casting was |
| 204 | carried out with a laboratory scale tape-casting machine (L800 by MTI) on a silicone-coated |
| 205 | PET film. Drying was performed in a low-temperature oven with no air blown to avoid cracks. |
| 206 | Table 1 shows the settings applied for tape casting. The button cells with 3 cm diameter |
| 207 | produced were co-sintered at 1280°C for 4 h with 1°C/min heating rate and an organic burnout |
| 208 | stage at 550°C. 10 g of dead-weight was used to ensure the cell flatness. During high |
| 209 | temperature sintering, Cl in the SnCl ₂ .H ₂ O is removed, leaving the oxides form. This has been |
| 210 | shown in XRD and XPS analysis in previous work in the same research group[22,60]. The |
| 211 | LSM cathode ink was produced using a three-roll mill machine (BUHLER) for mixing the |
| 212 | cathode powders with a Haraeus V-737 ink vehicle (22.6 vol% solids). The sintered half-cells |
| 213 | were hand-painted with a 15 μ m thick LSM layer with an effective area of 2 cm ² and sintered |
| 214 | again at 1100°C. |

247 2.2.2 Electrochemical Performance

The testing setup was similar to the one previously described in [53]. Leakage test carried out with He at 750°C prior to feeding with hydrogen. The cells were characterized for 24 h at 750°C in hydrogen by using 21 ml/min H₂ and 7 ml/min He, followed by 24 h in dry biogas at a flowrate of 14 ml/min CH₄, 7 ml/min CO₂ and 7 ml/minute He. The comparison was made using the open-circuit voltage (OCV), maximum power densities, and electrochemical impedance spectroscopy (EIS), measured in turns. EIS analysis was performed at 0.7 V within a frequency range of 0.1 Hz to 1M Hz with a signal amplitude of 10 mV.

255

256 2.2.3 Post-test Analysis

Microstructural analysis was conducted with a scanning electron microscopy (Hitachi 257 TM3030) with a magnification of 5k and acceleration of 15kV with unpolished and uncoated 258 fragments from tested SOFC cells. Temperature-programmed oxidation (TPO) tests were 259 conducted to quantify the amount of carbon in the SOFC-tested cells. 200gram of SOFC-tested 260 fragments were placed in the middle of a quartz chamber with compressed air flow rate of 50 261 262 ml/min for carbon oxidation. The furnace was ramped to 600°C at 5°C/min and annealed for 1 h to allow complete carbon oxidation. The outlet gas tube was connected to a mass 263 spectroscopy machine (MKS-Cirrus, USA) for evaluation. TPO was calibrated using three 264 known amounts of carbon graphite powder (10.1, 1.2 and 0.7 g) prior to the actual sampling. 265 The resulting CO₂ peak areas were used to construct a calibration curve (supplied in 266 supplementary material section). The calibrated value obtained used as a factor to quantity the 267 amount of carbon on the tested cells. 268

269

270

272 **3 Results and discussion**

273 **3.1 Effect of Sn Doping on Full-Cell Manufacturing**

The addition of SnCl₂.H₂O to the anode substrate slurry in either the first or second stage 274 resulted in a thick slurry, which cracked when completely dried (Figure 2). The mud-cracked 275 tape in Figure 2 originated from the uneven drying or drying gradient between the bulk of the 276 slurry and the skin of the tape. Blend-in doping with the tape-casting slurry was achieved by 277 introducing an additional premixing described in the methodology section. Mixing via ball 278 milling with only NiO powder increased the probability of Sn adherence to the Ni surface rather 279 280 than the ScSZ. The microstructural analysis of the sintered full cell (Figure 3a) revealed the microstructure of TSC (Sn-Ni/ScSZ cells) with dense electrolyte and porous anode substrate. 281 Figure 3c shows the anode substrate of TSC after NiO reduction, which created a more porous 282 structure compared with the anode substrate before reduction (Figure 3b). The average anode 283 porosity of TSC was 31.0%, which was higher than that of undoped cells (USC) (28.5%), 284 although the same setting was used. TSC1P (Sn-Ni/ScSZ with 1wt% pore former) and USC3P 285 (undoped Ni/ScSZ with 3wt% pore former) were fabricated with a final porosity volume of 286 38.5% and 39.8%, respectively. With the 55wt% solid loading used, the addition of more than 287 1wt% pore former in the Sn-Ni/ScSZ formulation resulted in a thick slurry, which limited 288 further addition of pore former. Increased porosity in the anode substrate leads to a decrease in 289 mass diffusion resistance, i.e higher performance, as long as the porosity level still within 290 291 optimum porosity level (<40%) [64,65]. Hence, due to the influence of Sn addition to porosity, cells with similar porosity levels were targeted and tested. 292

293

307

308 3.2 Electrochemical performance

309 3.2.1 Open circuit voltage

Initially in the hydrogen test, the test was run under OCV mode for six hours for complete 310 reduction of the cells while the first run of SOFC in biogas was 90 minutes in OCV mode to 311 minimise carbon deposition. The OCV measured alternately with iV curve, impedance, and 312 potentiostatic. Figure 4a shows that in TSC (Sn-Ni/ScSZ with 0 wt% pore former), the open-313 circuit voltage (OCV) in hydrogen was stabilized at 1.03 V 80 minutes after hydrogen was 314 315 introduced and gradually dropped to 1.02 V. With the fuel swap from hydrogen to biogas (BG), the OCV value was higher than that generated in hydrogen (1.05 V). Figure 4b shows the same 316 trend observed in TSC1P (Sn-Ni/ScSZ with 1 wt% pore former), whilst the opposite trend was 317

observed with the undoped Ni/ScSZ cells (USC and USC3P). OCV also increased in Sn–
Ni/YSZ cells reported previously by Troskialina et al. [27].

The Nernst equation for the electrochemical reaction for H₂ (Eq.1) is presented by Eq.8, which 320 in analogy also applies to Eq.7, the CO oxidation. E^0 is the open-circuit voltage (OCV), also 321 called the reversible potential or electromotive force (EMF), can be calculated from the Gibbs 322 free energy for the respective reaction and the Faraday constant as shown in Eq.9. Gibbs free 323 energy of CO oxidation at 750°C is higher than that of H₂ oxidation, which are –191.5 kJ/mol 324 and -193.6 kJ/mol [66], respectively. Substituting these values in Eq.9, the theoretical OCVs 325 at 750°C are 1.03V and 0.99V for H₂ and CO respectively. Higher OCV value from the CO 326 electrochemical oxidation expected to increase the OCV when biogas is used, but the OCV 327 dropped instead in the undoped cells. The difference in OCV value in biogas setup between the 328 Sn doped and undoped cells may reflect the difference in dry methane reforming (Eq.2b) 329 ability, which has higher OCV value as reported by You et al. [19]. 330

331

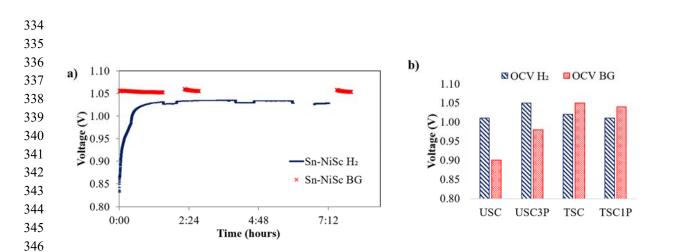

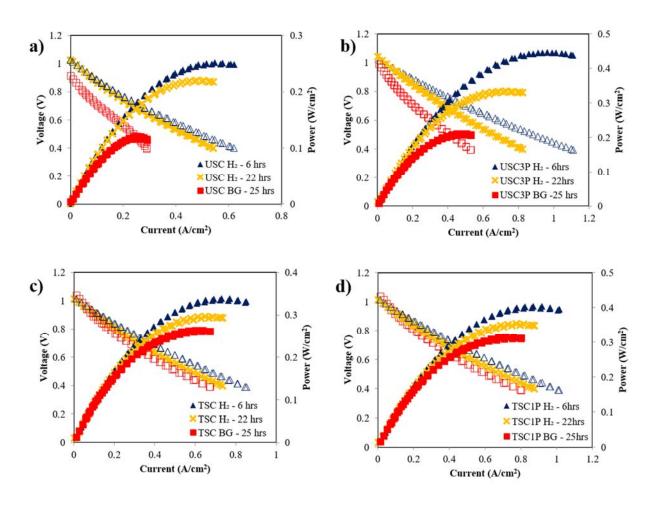

Figure 4. OCV when tested in hydrogen (H₂) and biogas (BG) of a) Sn–Ni/ScSZ SOFC cell
(TSC) and b) across different cells, Sn-doped and undoped cells.

350 3.2.2 Maximum power densities and impedance analysis

Figure 5 shows that the first maximum power densities obtained in hydrogen were 0.252, 0.450, 351 0.339, and 0.404 W/cm² for USC, USC3P, TSC, and TSC1P, respectively. In all cells, the 352 constant degradation observed in the *i*V–PV curve may be due to Ni coarsening in the cermet, 353 which reduces the catalytic surface area in the fuel cell. This well-known initial process in 354 SOFC has also been reported by Farrell et al.[8]. With an average 16% of cell degradation, the 355 maximum power densities in hydrogen before the fuel swap were 0.220, 0.331, 0.297, and 356 0.349 W/cm² for USC, USC3P, TSC, and TSC1P, respectively. US3P observed to have higher 357 358 degradation in hydrogen (Figure 5) compared to other cells. It is suspected to be due to the high porosity level, which near the maximum recommended limit (40%). Continuous Ni 359 coarsening and agglomeration may push the porosity limit, reduce the TPB volume, hence the 360 catalytic area and affected the effective conductivity[64,65]. The effect of porosity (Table 2) 361 on cell performance (Figure 5) was considerable, and less porous cells experienced high 362 resistance for the fuel to diffuse through the anode substrate (Figure 6). Hence, the slightly 363 lower performance of TSC1P in hydrogen compared with that of USC3P may be due to the 364 porosity level. The maximum power density of the latter was higher than that of the former. 365 Given the influence of Sn dopant to the cell's porosity, surface impregnation on sintered half 366 cells may be a more suitable method due to this limitation. 367

When the SOFCs were operated with biogas after the 24 hours test in hydrogen, the performance of the cells dropped. Sn-doped cells were less affected and showed an average of 11% drop in performance with the fuel swap, whilst undoped Ni/ScSZ cells exhibited 36% and 47% drop in performance for USC and USC3P, respectively. The maximum power densities in biogas were 0.116, 0.221, 0.263, and 0.314 W/cm² for USC, USC3P, TSC, and TSC1P, respectively. In the undoped cells, polarization increased with time in both hydrogen (0.032 Ω cm²) and biogas (0.14 Ω cm²). Surprisingly, the increase in biogas polarization in both TSC and TSC1P between 26 h and 46 h was not substantial ($0.030-0.035 \ \Omega cm^2$), as shown by the Nyquist plot in Figure 6. No impedance data were obtained for USC due to a spectrometer failure. Kan et al. [18] observed long-term stability with methane with Sn-doped Ni/YSZ cells, but the power density values obtained in methane operation between the undoped Ni/YSZ cells and doped Sn-Ni/YSZ cell were similar. Troskialina et al. [27] observed similar maximum power density under hydrogen and biogas via surface impregnation with pipette doping; the performance did not drop, which was also observed by Farrell et al. [8].

392 **3.3** Carbon deposition post-test analysis

393 3.3.1 SEM microstrucuture analysis

The microstructures of the anode of the undoped sample and Sn-doped cells are shown in 394 Figure 7. In both cases, the filamentous growth structures (circled in red) were visually 395 observed by SEM. Baker et al. [67] explained that filamentous carbon may have a graphitic 396 397 skin and an amorphous head end. A small amount of graphitic carbon enhances the performance by increasing the Ni anode conductivity via the additional graphitic carbon 398 network [68,69]. Carbon quantification with SEM–energy dispersive X-ray analysis (EDX) is 399 unreliable in this case because the electron signal is affected by the anode's uneven porous 400 structure. Hence, carbon quantification via temperature-programmed oxidation (TPO) was 401 used for evaluating the amount of carbon deposited, corresponding to the amount of CO₂ 402 released. 403

growth circled in red

- 408
- 409

410 3.3.2 Carbon quantification via temperature-programmed oxidation

The graphitic carbon burn-off in this work started at 520°C and completed the combustion at 411 600°C during the 1-hour dwelling stage (shown in the supplementary material). The CO₂ peaks 412 from the samples observed at 600°C (Figure 8) confirmed that the type of carbon build-up in 413 the samples were graphitic. In USC3P, smaller peaks at 400°C that might originate from 414 amorphous carbon was detected. The amounts of carbon deposited on TSC and TSC1P of Sn-415 NiScSZ samples were 4.83×10⁻³ and 5.94×10⁻³ mg-C/mg_{cat}, respectively, which were higher 416 than those of undoped Ni/ScSZ cells, USC and USC3P (1.49×10⁻³ and 2.60×10⁻³ mg-C/mg_{cat}). 417 The amount of carbon deposited and the rate of carbon deposition in the samples are presented 418 in Table 3. The carbon deposited and the rate of carbon deposition calculated in this work was 419 the net balance of carbon deposited, subtracting the amount of carbon oxidized to CO2 and CO 420 during the SOFC electrochemical reaction. The carbon deposition in Ni/ScSZ (40% Ni) anode 421 investigated by Somalu et al. [70] with a quartz tube and with an S/C ratio of 0.8 without 422 electrochemical reaction was 28 mg-C/mgcat. 423

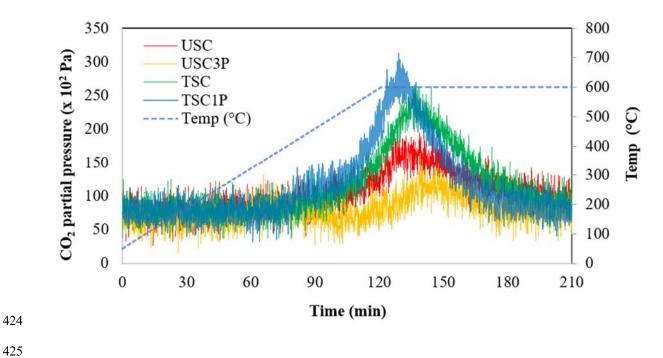

Figure 8. CO₂ peaks from carbon burn off on Sn–Ni/ScSZ and undoped Ni/ScSZ cells.

Table 3. Amount and rate of carbon deposition in undoped and Sn-doped NiScSZ cells.

| | Am | ount of carbon deposited | 430 Rate of carbon |
|-------|-----------------------|--|---|
| | Per sample (mg) | Per unit catalyst (mg-C/mg _{cat}) | deposition ⁴³¹ (mg-C/g _{cat} h) ₄₃₂ |
| USC | 0.300 | 1.49×10^{-3} | 0.062 |
| USC3P | 0.525 | 2.60×10^{-3} | 0.108 433 |
| TSC | 0.975 | 4.83×10^{-3} | 0.201 434 |
| TSC1P | 1.275 | 5.94×10^{-3} | 0.248 |

In the present work, although only one burn off temperature that deduced to be graphitic carbon from the burn off temperature (Figure 8), amorphous carbon may also have formed. As amorphous carbon is easier to oxidise, it may have oxidised either from CO₂ (Eq.4), or H₂O (Eq.5), or by oxidation from the electrochemical reaction (Eqs 1 and 6), hence only small amount of amorphous carbon detected in the USC3P in the TPO analysis.

Initially, the improved performance of Sn-NiScSZ suggested that the amount of carbon 442 deposited may be lower than that on the undoped cells due to the assumption that carbon 443 deposition may have hindered the electrochemical reaction. However, the result from TPO 444 showed otherwise. Thus, the decreased performance of undoped Ni/ScSZ cells in the present 445 study was not mainly due to the amount of carbon deposited but inclined to lack of methane 446 decomposition reaction (Eq. 3), hence lowered the amount of H₂. On the other hand, Sn 447 accelerated the activity of the methane decomposition reaction (Eq. 3), thereby releasing an 448 increased amount of H₂ as reactant for the electrochemical reaction and inevitably accompanied 449 450 by increased amounts of carbon. The result of this present study supported by Troskialina [71]. Troskialina [71] detected a higher amount of carbon in Sn-doped Ni/YSZ cells than in undoped 451 cells, with the carbon peak coinciding with the graphitic carbon burn-off temperature, as 452 observed in the present work. 453

454

In the present study, the author speculates that in the region with closer proximity to the 455 electrolyte (i.e the TPB/AFL area), rapid oxidation occurred due to increased electrochemical 456 reactions (Eq. 1) in response to increase amount of H₂. However, in case of carbon deposited 457 in further position (mainly in the anode substrate region), carbon might be oxidised only by 458 CO₂ (Eq. 4) or by H₂O (Eq. 5). In this case, the carbon oxidation by CO₂ (Eq. 4) and by H₂O 459 (Eq. 5) reaction rates might be slower than that of methane decomposition (Eq.3), leading to 460 461 increased carbon amount in Sn doped cells. Therefore, although small amount of graphitic carbon may still deposit near the TPB electrochemical reaction region, it did not hinder the 462 reaction. On the other hand, it may enhance the electrochemical reaction and electrical 463 conductivity by the extra graphitic network[68,69]. Nonetheless, even with assumption that the 464 TPB area is unaffected, excessive carbon build up in the substrate region must be avoided as it 465 will lead to stress, fracture the support, or push the metal particles off the support[39]. 466

The improve electrochemical performance of Sn doped cells in biogas compared with undoped 468 cells agreed with previous findings[18,27,42]. However, the high amount of carbon formed on 469 the Sn-doped cells in the present study was in contrast to the findings of Farrell et al.[8] and 470 the suggestion of Nikolla et al.[58] on the carbon oxidation ability. The significant difference 471 with this study compared to Nikolla et al.[58] and Farrell et al.[8] is the carbon ratios in the 472 473 hydrocarbon fuel. In present study, dry biogas is used, while Nikolla et al.[58] conducted the studies with moderate steam to carbon ratio with different fuels and Farrell et al.[8] used 474 475 ethanol, which has higher oxygen to carbon ratio. On other studies, Singh et al.[42] and Lay et al.[61] reported no significant performance difference and higher amounts of carbon observed 476 on the Sn doped cells compared to the undoped cells with either low steam to carbon ratio or 477 dry methane. 478

479

The surface impregnation method showed similar performance in hydrogen and biogas by the 480 Sn-NiYSZ anode when the fuel was switched from hydrogen to humidified methane and biogas 481 [42,71]. Through surface impregnation, almost all dopants adhere to the Ni on the anode 482 substrate surface, which may have better exposure in catalysing the dry reforming reaction as 483 well as increased the electrochemical reaction. On the other hand, doping by the slurry blend-484 in method practiced in present work may cause the Sn dopant to sit in the cermet bulk and thus 485 486 not be accessible. Hence, although dopant introduction can be performed easily with slurry blend in method, surface impregnation is more effective. Alternately, relative more dopant 487 would be required, and optimisation need to be carried out to statistically secure sufficient 488 presence on the nickel particle surfaces. Nonetheless, if the main aim of the research is on the 489 influence of Sn as dopant, surface impregnation method is recommended to eliminate the 490

influence of porosity to mass diffusion resistance and conductivity on the electrochemicalperformance.

493

494 **4** Conclusion

The electrochemical performance result suggested that Sn doping enhanced the performance 495 of Ni/ScSZ cells in biogas operation, due to improved catalytic activity of the methane 496 decomposition reaction, which is the first step in dry methane reforming reaction. The higher 497 amount of carbon deposited originated from slower carbon oxidation compared to the methane 498 499 decomposition reaction on Sn-Ni/ScSZ. From the higher amount of carbon affected by the methane decomposition reaction, we found no conclusive evidence on the positive influence 500 of Sn on carbon oxidation on Ni/ScSZ. In further work, a more in-depth understanding on the 501 effect of Sn addition in the dry reforming and carbon oxidation reactions may be possible 502 through prolonged SOFC electrochemical tests and separate reforming catalytic activity tests 503 with Sn-Ni/ScSZ cell with the exhaust gas connected to a gas chromatograph-mass 504 spectrometer. Separate conductivity tests in further work will also assist the understanding of 505 the effect of Sn to anode's porosity and conductivity. 506
