Abstract
Turbulent convective heat transfer coefficients of 9 wt% Al2O3/water and TiO2/water nanofluids inside a circular tube were investigated independently at the Royal Institute of Technology, KTH (Sweden) and at University of Birmingham (UK). The experimental data from both laboratories agreed very well and clearly show that Nusselt numbers are well correlated by the equations developed for single phase fluids with the thermophysical properties of nanofluid. The heat transfer coefficients of nanofluids can be compared with those of the base fluids at the same Reynolds number or at the same pumping power. As the same Reynolds number requires higher flow rate of nanofluids therefore such comparison shows up to 15% increase in heat transfer coefficient. However, at equal pumping power, the heat transfer coefficient of Al2O3 nanofluid was practically the same as that of water while that of TiO2 was about 10% lower. Comparing performance at equal Reynolds number is clearly misleading since the heat transfer coefficient can always be increased by increased pumping power; accordingly, the comparison between the fluids should be done at equal pumping power.

Keywords: nanofluids, convective heat transfer, turbulent, circular tube, Al2O3, TiO2, pumping power

Introduction
In the last decade the convective heat transfer of nanofluids in the turbulent flow was very frequently investigated and according to Science Direct, there were about 1000 articles investigating thermal performance of nanofluids in 2013 alone. Whilst there is still lack of consensus among scientists whether nanofluids show unusual thermal properties majority of papers claim that the presence small amount of nanoparticles drastically increases thermal conductivity and heat transfer coefficients [1][2][3].

Duangthongsuk and Wongwises [4] experimentally investigated the heat transfer and pressure drop in turbulent flow of TiO2/water nanofluids (0.2–2 vol% TiO2) in a horizontal double tube counter-
flow heat exchanger. They compared heat transfer coefficients in nanofluids with those in the base liquid at the same Re numbers (between 3000 and 18000) and observed 20–32% enhancement at 1.0% volume fraction of nanoparticles. However as the concentration of nanoparticles was increased to 2 vol% a reduction of the heat transfer coefficients by 14% was observed compared to base liquid.

Fotukian and Nasr Esfahany [5] investigated turbulent convective heat transfer in diluted γ-Al$_2$O$_3$/water nanofluids (Al$_2$O$_3$ < 0.2 vol%) in turbulent flow in a circular tube. They showed that, at the same Re number, heat transfer coefficients and pressure drops of nanofluids were higher than of the base fluid. A maximum increase of heat transfer coefficients by 48% was observed at volume fraction of nanoparticles of 0.054% and at Reynolds number of 10000.

Zamzamian et al. [6] investigated the effect of nanoparticles concentration and operating temperature on turbulent heat transfer coefficients in Al$_2$O$_3$/Ethylene Glycol (EG) and CuO/EG nanofluids (nanoparticles concentration between 0.1 and 1 wt%) in a double pipe and in a plate heat exchangers and reported an increase of heat transfer coefficients with the increase of particle concentration and operating temperature. They reported 3–49% enhancement of the heat transfer coefficients in nanofluids at the same Reynolds number.

Suresh et al. [7] investigated the heat transfer coefficient and friction factor in Al$_2$O$_3$/water nanofluids (0.3%, 0.4% and 0.5% Al$_2$O$_3$) in a turbulent flow through a straight pipe fitted with spiral inserts. At all Reynolds numbers, they observed almost the same values of the friction factors for the nanofluids as for the base fluids, and reported 10–48% enhancement in the Nusselt number in nanofluids at the same Reynolds number.

Fotukian and Nasr Esfahany [8] reported enhancement of the heat transfer coefficients by 25% and 20% increase of pressure drop in a turbulent flow of diluted CuO/water nanofluids (solid concentration larger than 0.3% v/v) in a circular tube comparing with water at the same Re number. They also found that the enhancement of heat transfer coefficient at all investigated Reynolds number was practically independent of the concentration of nanoparticles.

Sajadi and Kazemi [9] measured turbulent heat transfer coefficient and pressure drop in TiO$_2$/water nanofluid (TiO$_2$ volume fraction < 0.25%) in a circular tube and reported approximately 22% enhancement of the heat transfer coefficient and 25% increase in the pressure drop at Re=5000.

Turbulent convective heat transfer of the suspensions of γ-Al$_2$O$_3$, TiO$_2$ and CuO nanoparticles in aqueous solutions of carboxymethyl cellulose were investigated by Hojjat et al. [10]. They reported that the convective heat transfer coefficients in the nanofluids were higher than those in the base fluid when compared at equal Peclet numbers (Pe=Re×Pr) and that the heat transfer coefficient increases with the increase of Peclet number and nanoparticles concentration.

On the other hand, when compared at the same average velocity, the heat transfer coefficients of nanofluids were lower than those of the base fluids [11], [12]. The early work from Pak and Cho [11] showed that the heat transfer coefficient of alumina/water was up to 75% higher than the base fluid at the same Reynolds number, but it was 12% lower at the same average velocity. They argued that since the viscosity of nanofluids was higher than that of the base fluid, the Reynolds numbers of the nanofluids were lower than that of water at the same average velocity and consequently the heat
transfer coefficient was lower. The results of Pak and Cho [11] clearly indicated that the heat transfer coefficient enhancements of nanofluids depended on the method of comparing them with those of base fluids. Yu et al. [13] also reported the same conclusion.

Table 1 summarizes some works investigating turbulent heat transfer in nanofluids.

**Table 1 – Heat transfer in nanofluids in turbulent flow.**

Figure 1. Increase in heat transfer coefficient versus nanoparticles concentration compared at the same Re

Some of the reported enhancement of heat transfer coefficient (compared at the same Re) plotted against concentration of nanoparticles summarised in Fig. 1 and clearly show that there is no correlation between the two.

It is well known that there is no theory enabling explanation of unusual enhancement of thermal properties of nanofluids. Therefore in the great majority of the papers discussed above the experiments carried out by one research group are analysed and the results are presented as a graphs showing enhancement coefficients as a function of Re number or pumping power. In such a type of research there is very difficult, if possible at all, to verify experimental results.

In this paper we exploit the fact that the heat transfer in nanofluids was investigated in an EU sponsored project (NanoHex, Ref: 228882) by the consortium comprising universities, research establishment and companies. As it was already mentioned the bulk of experiments were carried out in B-ham and in Stockholm but all the results were heavily scrutinised by other members of the consortium during research meetings. This approach gives extra level of confidence as all the data presented in this paper were at least double/triple checked. Therefore the conclusions indicating that heat transfer coefficient in turbulent flow of nanofluid can be correlated by standard equations developed for ordinary fluids and that there is nothing unusual in thermal behaviour of nanofluids are sound.

**Materials and Methods**

**Materials**

The Al₂O₃ and TiO₂ nanofluids were supplied as concentrated suspensions (40 wt% for both) by ItN Nanovation AG (Germany) and Evonik AG (Germany), respectively. The concentrated suspensions were diluted to 9 wt% with distilled water (DW). Fig. 2 shows the TEM micrographs of Al₂O₃ and TiO₂ nanoparticles and Fig. 3 shows size distributions of nanoparticles/aggregates in the diluted suspension measured by dynamic light scattering (DLS). The physical properties of nanoparticles/nanofluids including pH, crystal phase, hydrodynamic particle size, average dry particle size (measured by TEM), and the concentration of additives (additives/surfactant) are summarized in Table 2.

**Figure 2 - TEM micrographs of tested nanofluids (a) Al₂O₃, (b) TiO₂**

**Figure 3 - Size distribution of Al₂O₃ and TiO₂ nanoparticles measured by dynamic light scattering (DLS)**
Table 2 Properties of investigated nanofluids

**Thermal conductivity and viscosity**

The thermal conductivity of the fluids was measured at KTH with a transient plane source (TPS) analyser (HotDisk model 2500) and with a transient hot wire (THW) analyser (KD2 Pro) at UBHAM. In both methods a sensor (No. 7577, TPS and KS-1, KD2 Pro) is immersed in the static liquid and thermal conductivity is calculated based on the analysis of transient temperature response to a low heat pulse. Moreover, a thermostat bath (accuracy better than ±0.01 ºC at KTH and ±0.1 ºC at UBHAM) was used in order to keep temperature equilibrium.

A coaxial cylinders’ viscometer (Brookfield model DV-II+Pro with UL adapter) was used at KTH and a plate-cone rheometer (AR 1000, TA Instruments, US) was used at UBHAM to measure the viscosity of the fluids. The shear rate was varied in the range 0 – 160 1/s and 10 – 100 1/s on KTH and UBHAM instruments respectively and the samples were placed in a thermostat bath with accuracy better than ±0.1 ºC to maintain temperature equilibrium.

**Experimental setup**

![Figure 4 - Experimental setup at (a) KTH and at (b) UBHAM](image)

Two closed-loop experimental rigs, one at KTH, Fig. 4a and one at UBHAM, Fig. 4b were used to measure heat transfer coefficients in turbulent flow in a pipe. In both rigs the test sections consist of entrance region, ensuring that the flow was fully developed at the beginning of heating section where the wall temperatures were measured, and a mixing section ensuring uniform cross section temperature after the outlet of the test section. The test section in KTH was heated by Joule effect whereas in UBHAM a heating tape was closely wrapped around the outer surface of the pipe (For details see [18]). Several thermocouples measured wall temperatures along the pipe as well as temperatures in the fluid at the inlet and the outlet. Furthermore, both experimental rigs included a pump, a flow-meter, cooling bath to cool down the working fluid and to adjust the temperature at the inlet of the test section. The necessary amount of fluid in the rig at KTH was 250-280 ml and 500 ml in the UBHAM rig. In the KTH rig, the pressure drop in the test section, including the inlet section, was measured by a differential pressure transducer (GE Druck, PTX5060-TA-A3-CC-H0-PA, UK). Data acquisition systems were used to collect and to transfer the data (temperatures, pressure difference, mass flow rates and densities) to a computer. At steady state, data was recorded every three seconds for about five minutes and this procedure was repeated three times both at KTH and UBHAM. The highest standard deviations for the average of the three individual measurements were 5.5% and 3.6% for KTH and UBHAM, respectively. **Table 3** summarises key parameters for both experimental rigs.

**Table 3 - Test loops parameters**

**Data reduction**

The local convective heat transfer coefficients, $h$, the local Nusselt numbers, $Nu$, and the heat flux were calculated from:
The average heat transfer coefficients were calculated as the area-weighted averages of the local heat transfer coefficients, and the average $Nu$ numbers were calculated from the average heat transfer coefficients. The friction factor was calculated as:

$$f = \frac{\Delta p}{\rho u^2/2} \cdot d$$

Furthermore, the theoretical pumping power (without considering the mechanical and the electrical losses in the pump) was calculated as the product of pressure drop ($\Delta p$) and volume flow rate ($\dot{V}$):

$$P = \Delta p \times \dot{V}$$

Nusselt number was calculated from Gnielinski correlation [19]:

$$Nu = \frac{(\frac{1}{\theta} (Re - 1000)Pr)}{1 + 12.7 \left( \frac{L}{d} \right)^{0.5} (Pr^{0.66 - 1})} \left[ 1 + \left( \frac{d}{L} \right)^{2} \right] \left( \frac{Pr}{Pr_{w}} \right)^{0.11}$$

And $f$, from Filonenko correlation, [20]:

$$f = (1.82 \log_{10} Re - 1.64)^{-2}$$

The density and specific heat of the nanofluids were calculated from:

$$\rho_{eff} = (1 - \phi_p)\rho_f + \phi_p \rho_p$$

$$C_{peff} = \frac{\phi_p C_{pf} + (1-\phi_p) \rho_p C_p}{\rho_{eff}}$$

Measured thermal conductivities of the nanofluids were compared with values calculated from Maxwell correlation for spherical particles [21]:

$$k_{eff} = \frac{k_p + 2k_b + 2(k_p - k_b)\phi}{k_p + 2k_b - (k_p - k_b)\phi} k_{bf}$$

Several models to calculate viscosity of nanofluids are suggested in the literature, but discrepancy in the results for similar materials [22] are significant. Therefore measured viscosities were used in calculating the Re and Pr numbers.

**Uncertainty analysis**

If $z$ is a function of several independent variables, $x_i$, each with their own uncertainties, $\Delta x_i$, the overall uncertainty in $z$ is calculated as [23]
\[ \Delta z = \pm \sqrt{ \sum_{i=1}^{n} \left( \frac{\partial f}{\partial x_i} \right)^2 (\Delta x_i)^2 } \]  

(11).

The expanded uncertainty is obtained by multiplying the overall uncertainty with the coverage factor \( \xi \):

\[ \Delta Z = \xi \Delta z \]  

(12).

By assuming the uncertainty of independent parameters (Table 4.a) the maximum uncertainty of dependent parameters with 95% confidence (\( \xi = 2 \)) for the friction factor and the pumping power and 99% confidence for the rest of variables (\( \xi = 3 \)) can be calculated (Table 4.b). The errors of the independent parameters are equal or less than stated in the table in both rigs.

**Table 4 - Uncertainty**

**Results and discussions**

**Thermal conductivity and viscosity**

To validate the instruments, the thermal conductivity and viscosity of distilled water (DW) were measured at KTH and UBHAM and the results are compared in Table 5 (reference values are also shown [24] [25]). There is very good agreement between the results obtained in KTH and UBHAM and the deviations are less than 2% for thermal conductivity and 4% for viscosity.

Measured thermal conductivity and viscosity of Al\(_2\)O\(_3\) and TiO\(_2\) nanofluids at 20 and 40°C and thermal conductivity calculated from Maxwell equation are summarised in Table 6. The differences between thermal conductivities measured in KTH and in UBAHM and values calculated from Maxwell correlation are below 2% but viscosity differs by 5-12%.

KTH measurements show that the relative thermal conductivity (thermal conductivity of nanofluid to base fluid) and the relative viscosity (viscosity of nanofluid to base fluid) of Al\(_2\)O\(_3\) nanofluids were 1.08 and 1.16 respectively and 1.07 and 1.24 for TiO\(_2\) nanofluids. UBHAM measurements indicate that relative thermal conductivity and relative viscosity of Al\(_2\)O\(_3\) nanofluids were 1.05 and 1.11 respectively and 1.05 and 1.22 for TiO\(_2\). Slight differences in the treatment and preparation of the nanofluids at the two universities may have affected the state of agglomeration differently and are thought to be the reason for larger deviations compared to water, particularly concerning the viscosity.

**Table 5 - Thermal conductivity and viscosity of distilled water at T=20°C and 40°C**

**Table 6 - Thermal conductivity and viscosity of nanofluids at T=20°C (a) and T=40°C (b)**

**Validation of convective heat transfer experimental setup**

To validate the experimental setup, the experimental results for distilled water were compared to those predicted by Eq. (6). Fig. 5a and Fig. 5b show the comparison of the experimental data with the predicted ones at inlet temperatures of 25°C and 40°C, respectively. Most of experimental data agree with the predicted value within +/- 10% and only few data points show deviation larger than 10% but less than 20%. The experimental average Nusselt numbers were calculated from the local
Nusselt numbers with appropriate values of thermal conductivity and viscosity based on IAPWS [24] [25]. Theoretical Nusselt numbers were calculated using thermophysical properties at the average fluid temperature between inlet and outlet. An analysis of literature data showed that Eq. 6 predicts most of 800 experimental data points within ±20% [26].

Figure 5 - Comparison of experimental average Nusselt number with Gnielinski correlation (Eq. 6) for distilled water (DW): \( T_{\text{inlet}}=25 \degree C \) (a), \( T_{\text{inlet}}=40 \degree C \) (b)

**Convective heat transfer coefficient of nanofluids**

Fig. 6 and Fig. 7 show the Nusselt numbers for \( \text{Al}_2\text{O}_3 \)/water and \( \text{TiO}_2 \)/water nanofluids, respectively, as a function of Reynolds number at two inlet temperatures 25 \degree C and 40 \degree C. The theoretical values in these figures were obtained from Eq. (6) with densities, specific heats, and thermal conductivities calculated from Eqs. (8), (9) and (10), respectively. Experimental viscosity values measured in KTH (Table 6) were used.

As shown in Fig. 6, the experimental data from KTH and UBHAM for \( \text{Al}_2\text{O}_3 \) nanofluid agree with the theoretical prediction within +/- 10%. At Reynolds numbers higher than 4000, the Nusselt numbers of \( \text{Al}_2\text{O}_3 \) nanofluid measured at KTH at higher inlet temperature (40 \degree C) are slightly higher than the predicted values with a maximum deviation of 19%. Most of UBHAM results, for the smaller range of Re, also fit well within +/- 10% of predictions. At the inlet temperature of 25 \degree C, the experimental data are slightly higher than the theoretical prediction, while at the inlet temperature of 40 \degree C, the experimental data are slightly lower than the theoretical prediction with a maximum deviation of less than 12%. Fig. 7 reveals similar trends for the \( \text{TiO}_2 \) nanofluids. Most of experimental data from both KTH and UBHAM at both inlet temperatures agree with the theoretical prediction within +/- 10%. In all cases, the deviations from the theoretical value are less than 20%, which is similar to the accuracy correlations for single phase fluids [26].

These results show that the agreement with Eq. (6) is better at the lower inlet temperature for both nanofluids (Fig. 6a and Fig. 7a) and for DW (Fig. 5a) than at the higher temperature (Fig. 5b, Fig. 6b and Fig. 7b). In summary, the results showed that Eq. (6) predicts the Nusselt number for the tested nanofluids with accuracy better than 20% in the temperature range 25-40 \degree C.

**Figure 6.** Comparison between the experimental average Nusselt numbers and Nusselt numbers calculated from Eq. (6) for \( \text{Al}_2\text{O}_3 \) nanofluid at 25 \degree C (a) and 40 \degree C (b)

**Figure 7.** Comparison between the experimental average Nusselt numbers and Nusselt numbers calculated from Eq. (6) for \( \text{TiO}_2 \) nanofluid at 25 \degree C (a) and 40 \degree C (b)

**Pressure drop**

The “ideal” pumping power was calculated from the measured flow rate and the pressure drop over the KTH-test section. Friction factors were then calculated from the measured pressure drop and the results were compared with the Eq. (7). Fig. 8 shows the friction factors as a function of Reynolds number for DW, \( \text{TiO}_2 \)/Water and \( \text{Al}_2\text{O}_3 \)/Water nanofluids at average temperatures in the range 25-55 \degree C. At Reynolds number higher than 4000 the friction factors calculated from the measured pressure drops are in a very good agreement with values predicted from Eq. (7) with a maximum deviation of...
±10%. Again correlation developed for simple (single phase) fluids can be used to predict pressure drop for nanofluids if the correct thermophysical properties of the nanofluids are used.

Figure 8. Friction factors based on experimental results compared to the Eq. (7) [20]

Comparing convective heat transfer of nanofluids at equal Reynolds number and at equal pumping power

As mentioned in the introduction, the assessment of thermal performance of nanofluids depends on the basis used to compare the heat transfer coefficient of nanofluids with that of the base fluid [13]. Fig. 9 and Fig. 10 compare heat transfer coefficients at equal Reynolds numbers for Al₂O₃ and TiO₂ nanofluids with those of distilled water at 25 °C and 40 °C, whilst Fig. 11 and Fig. 12 compare the heat transfer coefficients for these nanofluids at equal pumping power. In all cases, Eq. (7) was used to calculate the theoretical values of the Nusselt numbers, and the increase in heat transfer of nanofluid compared to base fluid is shown in percent (Fig. 9 – Fig. 12).

It is clear that the heat transfer coefficients in the nanofluids at the same Reynolds number are higher than those in the base fluid in both KTH and UBHAM experiments (Fig. 9 and Fig. 10). However, the experimental data from UBHAM show 4-8% enhancement of heat transfer coefficient whereas KTH data show 10-15% enhancement (see Fig. 9 and Fig. 10).

The differences between measured and predicted heat transfer coefficients in nanofluids at equal pumping power, shown in Fig. 11 and Fig. 12, are significantly lower than the differences at equal Reynolds number (Fig. 9 and Fig. 10) in both KTH and UBHAM results. Furthermore, the theoretical predictions based on Eq. (7) show reduction of heat transfer coefficients of nanofluids, compared with that for distilled water at the same pumping power.

The predicted heat transfer coefficients in Al₂O₃ is lower than in TiO₂ nanofluids (Fig. 9 and Fig. 10) what can be explained by higher viscosity for TiO₂ nanofluid therefore higher velocity to reach the same Reynolds number. On the other hand, when the basis of the comparison is the same pumping power (Fig. 11 and Fig. 12) the predicted heat transfer coefficient for TiO₂ nanofluid is much lower since it has higher viscosity.

Obviously it is very important to use the appropriate method when comparing heat transfer performance of nanofluids to that of their base fluids. Thermal comparison of nanofluids and base fluids should take into account both heat transfer coefficient and pressure drop therefore comparison at equal pumping power is appropriate. Comparison at the same Reynolds number suggests that any fluid with higher viscosity has higher heat transfer coefficients and therefore is better as a coolant. Therefore, comparing heat transfer coefficients of nanofluids and base fluids at equal Reynolds number, although common in the literature, is misleading and such comparisons should be ignored.

From the theoretical point of view, a nanofluid will show thermal benefit over the base fluid at the same pumping power if the thermal conductivity enhancement is sufficiently higher than the increase in viscosity. However, most literature data [11], [12], [27], [17], [18] and also the data in this work, showed that the increases in viscosity of various nanofluids (Al₂O₃, TiO₂, SiC, ZrO₂) were higher than their thermal conductivity enhancements. The results of Buongiorno et al. [28] showed that the
thermal conductivity of nanofluids can be predicted satisfactorily using the effective medium theory based model, i.e. Maxwell model. Based on this model, the thermal conductivity of nanofluids increases linearly with nanoparticle concentration:

$$\frac{k_{nf}}{k_{bf}} = 1 + 3\phi$$  \hspace{1cm} (11)

Similarly, the Einstein correlation can be considered as the lower limit of viscosity increase:

$$\frac{\mu_{nf}}{\mu_{bf}} = 1 + 2.5\phi$$  \hspace{1cm} (12)

However, most of literature data [22] showed that the viscosity of nanofluids increases non-linearly with nanoparticle concentration. Assuming the thermal conductivity and viscosity of nanofluids follows Eqs. (11) and (12), respectively, the maximum theoretical benefit of using nanofluids as a coolant in fully turbulent flow, instead of base fluid, for $\text{Al}_2\text{O}_3$ and $\text{TiO}_2$ nanofluids at the same pumping power in different volume concentrations is shown in Fig. 13. The advantage is very marginal and may not be sufficient in industrial applications considering the new problems of using nanofluid, such as sedimentation which may lead to blockage, erosion and corrosion of the cooling system.

**Figure 13.** Change in heat transfer coefficients for $\text{Al}_2\text{O}_3$ and $\text{TiO}_2$ nanofluids based on theoretical prediction at equal pumping power

**Conclusions**

Turbulent heat transfer in $\text{Al}_2\text{O}_3$/water and $\text{TiO}_2$/water nanofluids (9 wt% solid in both) in pipe circular tubes with constant heat flux at the walls was investigated experimentally at very similar conditions at KTH and UBHAM. It was found that when using the measured thermophysical properties of the nanofluids, correlations developed for simple fluids (Eq. 6 and Eq. 7) predict the Nusselt numbers and the friction factors in turbulent flow for all tested nanofluids within 20% and 10%, respectively. Therefore, from engineering point of view, both heat transfer and pressure drop of nanofluids can be predicted satisfactorily by using conventional correlations developed for single phase fluids.

The convective heat transfer coefficients of the nanofluids were compared with those of the base fluids at equal Reynolds number and at equal pumping power. Comparison at equal Reynolds number showed that the thermal performance of nanofluid with higher viscosity was better since
higher volumetric flow rate was required to achieve the same Reynolds number. From a practical point of view, this is not a relevant comparison, as heat transfer can always be increased by increasing the flow rate. Although misleading, this method of comparison is still common in the literature [29], [30], [31], [32]. Evaluation of the heat transfer performance of the nanofluids at equal pumping power seems to be appropriate approach from industrial point of view as it takes into account the total cost to remove heat from the system, i.e. the pumping cost. Based on this criterion, both Al\textsubscript{2}O\textsubscript{3} and TiO\textsubscript{2} nanofluids investigated in this work did not show any benefit for cooling applications in turbulent flow since the increases in viscosities were higher than the enhancements of heat transfer coefficient.

(a)

(b)
The graph shows the increase in concentration (%) as a function of concentration (vol%) for two different materials: Al$_2$O$_3$ (solid line) and TiO$_2$ (dashed line). The concentration range is from 0 to 5 vol%, and the increase range is from 0 to 5%.
Highlights

- Turbulent heat transfer of nanofluids at similar conditions was investigated at two universities.
- Nusselt numbers and friction factors in nanofluids can be predicted by single phase fluid correlations.
- Comparison heat transfer coefficients of nanofluids and base fluids at equal Reynolds number is misleading.
- This comparison at equal pumping power is an appropriate approach and takes into account the total cost of the system.
- Based on the correct criterion this work show no benefit for cooling application with nanofluids in turbulent flow.
