## Abstract

There is cumulative evidence that young people in an “at risk mental state” (ARMS) for psychosis show structural brain abnormalities in fronto-limbic areas, comparable to, but less extensive than those reported in established schizophrenia. However, most available data come from ARMS samples from Australia, Europe and North America while large studies from other populations are missing. We conducted a structural brain magnetic resonance imaging (MRI) study from a relatively large sample of 69 ARMS individuals and 32 matched healthy controls recruited from Singapore as part of the Longitudinal Youth At-Risk Study (LYRIKS). We used two complementary approaches: a voxel-based morphometry (VBM) and a surface-based morphometry (SBM) analysis to extract regional gray and white matter volumes (GMV and WMV) and cortical thickness (CT). At the whole brain-level, we did not find any statistically significant difference between ARMS and healthy controls (HC) groups concerning total GMV and WMV or regional GMV, WMV and CT. The additional comparison of two regions of interest, hippocampal and ventricular volumes, did not return any significant difference either. Several characteristics of the LYRIKS sample like Asian origins or the absence of current illicit drug use could explain, alone or in conjunction the negative findings and suggest that there may be no dramatic volumetric or cortical thickness abnormalities in ARMS.

## 64 Introduction

65 Adolescents and young adults in the putative prodrome of psychotic illness – variously  
66 labeled as being at "ultra high risk" (UHR), "clinical high risk" (CHR), or in an "at risk mental  
67 state" (ARMS) – experience distressing sub-threshold psychotic symptoms and have a 30-43% risk  
68 of transition to psychosis over a 36 month-period<sup>1</sup>. These individuals are typically identified  
69 through clinical assessment of help-seeking individuals who present (i) attenuated or (ii) brief and  
70 intermittent psychotic symptoms, or (iii) a decrease in global functioning combined with a genetic  
71 risk for psychosis<sup>2,3</sup>.

72 Structural MRI brain studies have featured prominently in attempts to identify biomarkers of  
73 ARMS. In general, this work has shown baseline grey matter volume (GMV) reductions in frontal,  
74 temporal and limbic areas of ARMS individuals<sup>4-10</sup>. Though the results of ARMS MRI research,  
75 typically obtained in small samples, are heterogeneous and contradictory<sup>11,12</sup>, many of the  
76 identified brain changes are similar to those seen in patients with established schizophrenia<sup>13,14</sup>.  
77 Some GMV reductions, particularly in fronto-limbic areas, have been confirmed to be statistically  
78 robust through meta-analysis<sup>15</sup> and multi-centre investigations<sup>16</sup>.

79 In parallel to GMV findings, only four whole-brain studies compared cortical thickness  
80 between ARMS individuals and controls and their results were divergent. One study reported  
81 cortical thinning in several brain regions, including frontal, temporal and limbic areas<sup>17</sup> while three  
82 studies did not report any cortical thinning significant at the whole-brain level in a larger sample of  
83 ARMS individuals when compared at baseline with healthy controls (HC)<sup>18-20</sup>.

84 Fewer studies have investigated alterations of white matter volume (WMV) in ARMS but  
85 their findings are consistent with what has been reported for GMV. They reported smaller WMV in  
86 fronto-temporo-limbic areas<sup>5,6,21</sup> as well as a global reduction of WM growth over time<sup>22</sup> in ARMS  
87 compared to HC.

88 While baseline comparisons between ARMS and HC are useful for identifying putative  
89 biomarkers of young people in need of care, the majority of ARMS individuals do not transition to

1  
2 90 frank psychosis (ARMS-NT), spurring attempts to identify ARMS individuals at incipient risk of  
3  
4 91 psychosis onset (ARMS-T). At the whole-brain level, gray matter differences associated with  
5  
6 92 transition to psychosis have been localized in the same fronto-temporo-limbic regions that also  
7  
8 93 distinguish the overall ARMS group (regardless of transition) from HC <sup>4,6,23,24</sup>. More precisely,  
9  
10 94 baseline GMV reductions in ARMS-T when compared to ARMS-NT were especially consistent in  
11  
12 95 the fronto-insular and superior temporal regions <sup>15</sup>.

13  
14  
15 96 All these studies recruited ARMS samples from North America, Europe and Australia. There  
16  
17 97 are few structural brain MRI studies performed in ARMS samples from Asia and all were  
18  
19 98 conducted in small cohorts <sup>17,25,26</sup>. Nevertheless, establishing consistency across different ethnic  
20  
21 99 groups represents a critical step in the development of any putative biomarkers.

22  
23  
24 100 An additional advantage of such research in Asian countries is the very low prevalence of  
25  
26 101 cannabis and other drug use <sup>27</sup>. Substance use is more frequent in patients with psychotic disorders  
27  
28 102 in Western countries <sup>28</sup> and could be a problematic confound for ARMS research in Western  
29  
30 103 populations <sup>29,30</sup>. Substance use, and cannabis in particular, have been associated with structural  
31  
32 104 changes in at-risk populations <sup>31-34</sup>.

33  
34  
35 105 We used both voxel-based (VBM) and surface-based (SBM) morphometry analyses to run a  
36  
37 106 comprehensive and not regionally biased whole-brain investigation of baseline GMV, WMV, and  
38  
39 107 cortical thickness (CT) alterations in a relatively large sample of 69 ARMS individuals with  
40  
41 108 minimum antipsychotics or substance use recruited from Singapore as part of the Longitudinal  
42  
43 109 Youth At-Risk Study (LYRIKS) <sup>35</sup>. Given the good statistical power offered by our large sample  
44  
45 110 size, we hypothesized that we should reproduce some of the grey and white matter volume and  
46  
47 111 cortical thickness alterations in the frontal and temporal lobes as reported by previous whole-brain  
48  
49 112 studies.

## 113 **Methods and Materials**

### 114 **Participants**

115 Our sample comprised 75 ARMS subjects and 40 HC between 14 and 29 years old, matched  
116 for age, gender, handedness and educational level. The participants were part of the Longitudinal  
117 Youth At-Risk Study (LYRIKS), in Singapore. ARMS subjects were recruited from programs  
118 targeted at identifying individuals at-risk for developing psychosis run by the Institute of Mental  
119 Health, and from various community mental health agencies. Details of the recruitment strategy  
120 were previously reported<sup>36</sup>. In brief, we adopted an active approach of recruiting individuals from  
121 various psychiatric clinics and community mental health agencies, and a passive approach of self-  
122 referrals from print and social media advertisements. ARMS subjects met inclusion criteria for the  
123 prodromal state of schizophrenia in accordance to the comprehensive assessment of at-risk mental  
124 states (CAARMS)<sup>3</sup>. CAARMS assessments were performed by experienced psychometricians that  
125 were trained at ORYGEN in Melbourne. Inter-rater reliability was established and monthly  
126 supervisions were conducted throughout the study period to guarantee diagnostic validity. At-risk  
127 participants had no history of psychiatric, neurological or serious medical disorders, or mental  
128 retardation; and were not on antipsychotic medications. We excluded anyone with a current  
129 substance abuse as defined by the DSM-IV. Six ARMS subjects and 1 HC had a past history of  
130 substance use disorder (Table 1). 6 ARMS subjects and 8 HC were excluded from the original  
131 sample due to the use of a different T1-weighted structural MRI sequence (n=10) or the presence of  
132 gross structural abnormalities or movement artifacts (n=4). The demographics and clinical  
133 information of the remaining 69 ARMS and 32 HC are detailed in Table 1. Out of 69 ARMS  
134 subjects, 33 had a concomitant diagnostic of depression and/or anxiety and 37 were medicated with  
135 antidepressants, mostly selective serotonin reuptake inhibitor (SSRI, n=28), but also non-SSRI  
136 (n=7) or both SSRI and non-SSRI in association (n=2). During 28-month follow-up, 7 ARMS  
137 subjects converted to psychosis and 13 withdrew from the study, leaving a final sample of 56  
138 ARMS-NT and 7 ARMS-T at baseline.

1  
2 139 Additional exclusion criteria for controls were: (i) history of severe head injury, (ii) personal  
3  
4 140 history of psychotic disorder, (iii) and personal history of other neuropsychiatric disorder. Controls  
5  
6 141 did not have any family history of neuropsychiatric disorders, except, three controls had a first-  
7  
8 142 degree relative with a history of depression, two had a second-degree relative with history of  
9  
10 143 schizophrenia (n=1) or depression (n=1). In both the ARMS and HC groups, Primary School  
11  
12 144 Leaving Examination (PSLE) scores, which are the result of a standardized multidisciplinary test of  
13  
14 145 scholastic achievement, were used as a measure of educational level. Written informed consent was  
15  
16 146 provided by all participants aged 21 and above or from a legally acceptable representative for  
17  
18 147 participants under 21 with participant's assent. Ethics approval for this study was provided by the  
19  
20 148 National Healthcare Group's Domain Specific Review Board.  
21  
22  
23  
24 149

## 25 26 150 **Image acquisition**

27  
28 151 T1-weighted structural MRI data were obtained from a 3T Siemens Trio Tim scanner  
29  
30 152 (Siemens, Erlangen, Germany) at the Center for Cognitive Neuroscience, Duke-NUS Graduate  
31  
32 153 Medical School, Singapore. The principal sequence relevant to this study was a T1-weighted 3-D  
33  
34 154 magnetization-prepared rapid-acquisition gradient echo (MPRAGE) sequence optimized for grey-  
35  
36 155 white matter contrast. It was identical to that used by the Alzheimer's Disease Neuroimaging  
37  
38 156 Initiative ADNI consortium<sup>37</sup>. Parameters were as follows: TR = 2300 ms, TE = 2.98 ms, TI = 900  
39  
40 157 ms, flip angle = 9°, BW = 240 Hz / pixel, FOV = 256 × 240 mm, Matrix = 256 × 240; resulting  
41  
42 158 voxel dimensions: 1.0 × 1.0 × 1.0 mm, acquisition time 5 min 03 sec. Parallel imaging was used to  
43  
44 159 improve the signal-to-noise ratio instead of shortening the scan time. We obtained a single high-  
45  
46 160 quality image instead of averaging two or more rapidly acquired images. Images were inspected for  
47  
48 161 motion artifact at the time of acquisition and scanning was repeated as necessary. Images were  
49  
50 162 reviewed for any gross pathological findings.  
51  
52  
53  
54  
55 163

## 56 57 164 **Voxel-based morphometry**

1  
2 165 Every scan was visually checked to exclude the presence of artifacts or gross anatomical  
3  
4 166 abnormalities that could impact image pre-processing. Voxelwise analyses of brain GMV and  
5  
6 167 WMV differences were conducted using the DARTEL (Diffeomorphic Anatomical Registration  
7  
8 168 Through Exponentiated Lie Algebra) procedure<sup>38</sup> implemented in SPM8  
9  
10 169 (<http://www.fil.ion.ucl.ac.uk/spm/software/spm8/>) running under MATLAB 2009b  
11  
12 170 (<http://www.mathworks.com.au/products/matlab/>). Briefly, each participant's T1-weighted  
13  
14 171 anatomical scan was segmented into distinct tissue compartments (i.e. GMV and WMV) and  
15  
16 172 spatially normalized via a non-linear algorithm using a unified procedure<sup>38</sup>. A study-specific  
17  
18 173 template was then generated by normalizing each participant's segmented grey or white matter  
19  
20 174 image to a common space. Native-space grey or white matter images were then spatially normalized  
21  
22 175 to this template. Jacobian modulation of voxel intensities was employed to preserve grey or white  
23  
24 176 matter volumes. The images were smoothed with an 8 mm full-width-half-maximum Gaussian  
25  
26 177 kernel prior to statistical analysis.

27  
28  
29  
30 178 The General Linear Model (GLM) was used to test for group differences in volume at each  
31  
32 179 voxel, as implemented in Randomise (<http://fsl.fmrib.ox.ac.uk>). All results were corrected for  
33  
34 180 multiple comparison type I error with a non-parametric cluster-size based procedure<sup>39,40</sup>. A voxel-  
35  
36 181 wise threshold was initially set to 0.001 to compromise between sensitivity to spatially extended vs.  
37  
38 182 focal and intense differences. Then, a cluster-size threshold was calculated via permutation testing  
39  
40 183 (10,000 permutations). We compared baseline GMV and WMV between ARMS group and HC  
41  
42 184 group, while covarying for age, gender, intracranial volume (ICV), handedness and ethnicity.  
43

45  
46  
47

#### 48 186 **Surface-based morphometry**

49  
50 187 The semi-automated cortical thickness measurements were performed using FreeSurfer v5.1.0  
51  
52 188 (<http://surfer.nmr.mgh.harvard.edu/>; Martinos Imaging Centre, Charlestown MA), as described by  
53  
54 189 Dale, Fischl and colleagues<sup>41,42</sup>.

1  
2 190 The white (i.e., gray-white matter boundary) and pial (gray-cerebrospinal fluid boundary)  
3  
4 191 surfaces were visually inspected and edited, where necessary, using standard procedures  
5  
6 192 (<http://surfer.nmr.mgh.harvard.edu/fswiki/Edits>), blind to diagnostic status. Surfaces for each  
7  
8 193 participant were registered to a study specific template and smoothed using a Gaussian kernel of 25  
9  
10 194 mm prior to group analysis.

11  
12 195 We used a GLM implemented in Freesurfer to estimate group differences in cortical thickness  
13  
14 196 at each vertex of the cerebral surface while controlling for the effect of age, gender, handedness,  
15  
16 197 and ethnicity. Right and left hemispheres were tested separately. False Discovery Rate (FDR)  $p <$   
17  
18 198 0.05 was used for multiple comparison correction.  
19  
20  
21

22 199

#### 23 24 200 **Volume-of-interests measurements**

25  
26 201 We derived five volume-of-interests measurements from the Freesurfer analysis: total  
27  
28 202 intracranial volume (ICV), total GMV, total WMV, hippocampal volume, and ventricular volume.  
29  
30 203 ICV was calculated using a validated method described elsewhere<sup>43</sup>. Total ventricular volume was  
31  
32 204 defined as the total volume of lateral ventricles, third ventricle, fourth ventricle, and fifth ventricle.  
33  
34

35 205 Statistical analyses were performed with the Statistical Package for the Social Sciences,  
36  
37 206 version 21 (SPSS 21.0, IBM Corp. Armonk, NY, USA). Differences in cerebral volume were tested  
38  
39 207 using one-way analysis of covariance (ANCOVA) with age, gender, handedness, ethnicity, and ICV  
40  
41 208 as covariates.

59  
60

## 211 **Results**

### 212 **Demographics and volume-of-interest differences**

213       There was no group difference in sociodemographics (age, gender, handedness, ethnicity, and  
214 educational level) or past history of substance use disorder (Table 1). No group difference in  
215 intracranial volume (ICV), total GMV, total WMV, hippocampal volume or ventricular volume  
216 between ARMS and HC was observed (Table 1).

217

### 218 **GMV and WMV differences between ARMS subjects and healthy controls**

219       We found no regional GMV or WMV differences between ARMS and HC (i.e., voxel-wise  
220 clustering-forming threshold of  $p < 0.001$  and  $p < 0.05$  corrected at the cluster level). Lowering the  
221 initial voxel-wise cluster-forming threshold to  $p < 0.01$  did not return significant group differences  
222 either ( $p < 0.05$  corrected at the cluster level).

223       At a voxel-wise threshold of  $p < 0.001$  and  $k > 10$  voxels (uncorrected at the cluster level), we  
224 found one cluster of increased GMV on the right precentral gyrus ( $k = 88$  voxels,  $t_{\text{peak}} = 3.64$ ,  
225 MNI = 4, 9, 44) and a second cluster of decreased GMV on the right frontal inferior gyrus ( $k = 17$   
226 voxels,  $t_{\text{peak}} = 3.58$ , MNI = 46, 15, 21) in ARMS when compared to HC.

227

### 228 **Cortical thickness differences between ARMS subjects and healthy controls**

229       We found no regional cortical thickness differences between ARMS and HC at  $p < 0.05$  (FDR  
230 corrected). At a voxel-wise cluster-forming threshold of  $p < 0.001$  (uncorrected at the cluster level)  
231 we found one cluster of increased cortical thickness on the right frontal pole in ARMS when  
232 compared to HC ( $k = 230$  vertices,  $t_{\text{peak}} = 3.78$ , MNI = 21, 69, -2).

233

### 234 **Conversion to psychosis**

235       We found no significant difference between HC and ARMS-T, or between ARMS-T and  
236 ARMS-NT concerning GMV, WMV, cortical thickness or VOI analyses based on the same set of

1  
2 237 thresholds. For the VBM analysis, lowering the initial voxel-wise cluster-forming threshold to  $p <$   
3  
4 238 0.01 ( $p < 0.05$  corrected at the cluster level) did not return significant group differences either.

5  
6 239

7  
8 240 **Comorbid depression and anxiety disorders.**

9  
10 241 To investigate structural differences that could be related to anxio-depressive disorders and  
11  
12 242 that affect a large proportion of AMRS individuals, we compared GMV, WMV, CT and VOI  
13  
14 243 between ARMS with a concomitant diagnostic of depression and/or anxiety ( $n = 33$ ) and ARMS  
15  
16 244 without ( $n = 36$ ). We found no significant differences. An additional comparison of GMV, WMV,  
17  
18 245 CT, and VOI between ARMS individuals with antidepressant ( $n = 37$ ) and those without ( $n = 32$ )  
19  
20 246 found no significant difference either.

## 248 Discussion

249 Although there is evidence for the involvement of frontal, temporal and limbic areas in  
250 ARMS for psychosis, the sample size of previous studies is often modest and findings mainly  
251 concern ARMS samples from Western countries. In this study, we examined brain structural  
252 changes in a large sample of 69 ARMS subjects recruited in Singapore, and for which potential  
253 biases introduced by drug use, including antipsychotics and cannabis, were well controlled.  
254 Comparison of regional GMV, WMV, and CT as well as ventricular and hippocampal volumes  
255 between ARMS individuals and HC revealed no significant differences. The further analysis of the  
256 same structures between ARMS-T and ARMS-NT as well as between ARMS-T and HC did not  
257 return any positive result either.

258 Regional reductions of GMV in ARMS subjects are the most common findings in whole-  
259 brain VBM studies<sup>15,44</sup>. Only 3 whole-brain VBM studies reported negative findings but their  
260 ARMS sample was either unusually young (12-18 years old)<sup>20,22</sup> or small (n=14)<sup>26</sup>. Concerning  
261 CT, only one previous study<sup>18</sup> used the same preprocessing technique (Freesurfer), while three  
262 others<sup>17,19,20</sup> used a different algorithm: CLASP<sup>45</sup> or voxel-based cortical thickness<sup>46</sup>. Their  
263 findings were divergent, reporting either extended<sup>17</sup> or no CT differences at the whole-brain level  
264<sup>18-20</sup> in ARMS subjects when compared to HC at baseline. Our results are consistent with the  
265 absence of cross-sectional difference between ARMS subject and HC at the whole-brain level  
266 reported by the three largest studies<sup>18,19,22</sup>. Additional comparison of hippocampal volumes  
267 between ARMS and HC showed no significant difference as well. Reduced hippocampal volume is  
268 a frequent finding from region-of-interest studies in ARMS samples<sup>47-51</sup> and has been shown to be  
269 statistically significant at the whole-brain level in one VBM study<sup>4</sup>, although some inconsistencies  
270 have also been reported<sup>52,53</sup>. The higher sensitivity of manual tracing methods to detect volumetric  
271 changes in medial temporal structures could explain our inability to replicate hippocampal volume  
272 reduction often reported by manually traced region-of-interest studies in ARMS samples. However,

1  
2 273 Freesurfer automated segmentation performance has been shown to produce volumetric data that  
3  
4 274 were very close to those obtained with the “gold standard” manual tracing method<sup>54</sup>.

5  
6 275 The sensitivity of our analyses did not improve when specifically comparing ARMS-T with  
7  
8 276 HC or ARMS-NT. However, these additional group comparisons were clearly underpowered due to  
9  
10 277 the small number of subject in the ARMS-T group (n = 7). A recent well powered study has also  
11  
12 278 reported the absence of structural abnormalities in ARMS-T when compared to ARMS-NT at the  
13  
14 279 whole brain level<sup>19</sup>. There was lack of evidence on the structural differences between ARMS-T and  
15  
16 280 ARMS-NT or HC at the baseline.

17  
18  
19 281 The absence of relationship between clinical high-risk status (regardless of later transition or  
20  
21 282 non-transition to psychosis) and brain structure might be attributed to unique characteristics of  
22  
23 283 LYRIKS. Understanding the local pathways to care for the ARMS subjects is an important area of  
24  
25 284 work, and efforts are currently underway. In a previous publication, we found that LYRIKS sample,  
26  
27 285 was comparable to other samples from the UK or Australia concerning social and clinical profiles  
28  
29 286<sup>35</sup>. Accordingly, clinical characteristics reported in Table 1 (i.e., CAARMS ratings, grouping and  
30  
31 287 comorbidities) are also comparable to those from OASIS and PACE samples<sup>55</sup>, although the rate of  
32  
33 288 conversion to psychosis (i.e., 10% at 28-month) is probably among the lowest reported<sup>1</sup>. However,  
34  
35 289 ethnicity differences might be contributing to the negative findings as most participants in the  
36  
37 290 LYRIKS sample have Asian origins. Another interesting difference could be the relative lack of  
38  
39 291 drug use, including cannabis and/or antipsychotics in our sample. Half the ARMS individuals were  
40  
41 292 pharmacologically treated for depression and/or anxiety and both the medication and the affective  
42  
43 293 disorder could potentially impact brain structure. Last, the relatively conservative whole-brain  
44  
45 294 approach could explain divergences with other region-of-interest studies. These four points are  
46  
47 295 developed below.

48  
49  
50  
51  
52 296

53  
54  
55 297 **Ethnicity**

1  
2 298 It is widely recognized that the expression of psychotic symptoms varies among ethnic groups  
3  
4 299 <sup>56,57</sup>. Although these disparities seem more related to psychosocial inequalities than to ancestry  
5  
6 300 differences <sup>58</sup>, it raised the idea that ethnical differences could be instructive regarding the  
7  
8 301 pathogenesis of schizophrenia <sup>59</sup>. Accordingly, a structural MRI study reported an effect of ethnicity  
9  
10 302 on gray-matter findings following a first episode of psychosis <sup>60</sup>. These neuroimaging findings  
11  
12 303 should be interpreted with caution regarding the modest sample size and the abundance of possible  
13  
14 304 confounds, nevertheless, they suggest that some neuroanatomical features of psychosis could be  
15  
16 305 specific to the ethnic group under investigation. In general, it is not very likely that our negative  
17  
18 306 findings are attributable to the ethnical characteristics of our sample alone. Nevertheless, a different  
19  
20 307 genetic background may modify the susceptibility of the brain to different etiological factors <sup>61</sup> and  
21  
22 308 could impact the neuroanatomical correlates of the pathophysiological process.  
23  
24  
25  
26  
27

### 28 310 **Drugs**

29  
30 311 Singapore has the second lowest annual prevalence of cannabis-use worldwide (0.005 in  
31  
32 312 2006) <sup>62</sup> and no participant in our sample reported current illicit drug use. While most neuroimaging  
33  
34 313 studies in ARMS excluded subjects with current and/or past substance abuse and/or dependence  
35  
36 314 regarding the DSM or the International Classification of Diseases (ICD), they possibly included  
37  
38 315 cannabis users as long as they did not fulfill the criteria for abuse of dependence. Only few studies  
39  
40 316 specified the proportion of cannabis users in their sample but the reported rate can be as high as 35  
41  
42 317 % for current use <sup>9,63</sup> and up to 70% for a history of cannabis use <sup>10</sup>. In these previous studies, the  
43  
44 318 prevalence of cannabis use did not statistically differ between ARMS subjects and controls,  
45  
46 319 suggesting that neuroimaging findings were not driven by cannabis use only. Nevertheless, this  
47  
48 320 does not exclude the possibility that cannabis use could act as a risk-modifying factor by interacting  
49  
50 321 with other risk factors like genetics and have more dramatic consequences in the group of ARMS  
51  
52 322 than in healthy controls <sup>64,65</sup>. Accordingly, three recent studies in early psychosis have shown that  
53  
54 323 the amount of grey matter loss in the cingulate cortex was either positively correlated with  
55  
56  
57  
58  
59  
60

1  
2 324 cannabis-use<sup>34,66</sup> or restricted to cannabis-users only<sup>67</sup>. Moreover, the hippocampus is rich in  
3  
4 325 endocannabinoid receptors and hippocampal volume reduction has been strongly associated with  
5  
6 326 cannabis use in a recent meta-analysis<sup>68</sup>, suggesting that the absence of hippocampal atrophy in our  
7  
8 327 sample may be partly related to the relative lack of cannabis use.

10 328 Antipsychotics are another potential confounding factor because they have been shown to  
11  
12 329 alter GMV in schizophrenia after both continued<sup>69</sup> and short-term treatment<sup>70</sup> administration. In  
13  
14 330 this study, we can exclude the potential influence of antipsychotic treatment on our results as only 3  
15  
16 331 subjects received a very small dose (< 15mg week of haloperidol equivalent). However, the absence  
17  
18 332 of antipsychotic use is unlikely to explain our negative findings, given the results of a recent meta-  
19  
20 333 analysis indicating an effect of antipsychotics on GMV in the opposite direction (i.e., antipsychotics  
21  
22 334 reverse the GMV reductions associated with a greater risk of transition to psychosis)<sup>15</sup>.

23  
24  
25  
26 335

### 27 28 336 **Affective comorbidity**

29  
30 337 Approximately half of ARMS individuals in our sample had a comorbid depressive and/or  
31  
32 338 anxious disorder, a proportion that is comparable with other ARMS samples<sup>55</sup>. Disentangling  
33  
34 339 emerging psychosis with concomitant mood disturbances from depression or anxiety with  
35  
36 340 attenuated psychotic symptoms is challenging from both a clinical and neuroanatomical point of  
37  
38 341 view. Similarly to psychosis, affective disorders may also show neuroanatomical features within  
39  
40 342 medial prefrontal and medial temporal structures<sup>71</sup> and this could represent an important source of  
41  
42 343 confound for neurostructural findings in ARMS. Accordingly, a recent study showed that comorbid  
43  
44 344 depression and anxiety may contribute to GMV reduction in the anterior cingulate cortex in ARMS  
45  
46 345<sup>72</sup>. In our sample, we did not find any effect of comorbid depression and/or anxiety or  
47  
48 346 antidepressant treatment on regional GMV, WMV, CT or VOI. However, we cannot exclude that  
49  
50 347 antidepressant treatment may have interfered with the natural course of ARMS individuals<sup>73,74</sup>.

51  
52  
53  
54 348

### 55 56 349 **Whole-brain analysis**

1  
2 350 We made the initial choice of a whole-brain analysis because it is a common and well  
3  
4 351 accepted statistical approach for both VBM and SBM analyses. Moreover, in the context of an  
5  
6 352 excess of significance in the neuroimaging literature <sup>75,76</sup>, the whole-brain approach limits the risk  
7  
8 353 of publication bias toward positive findings that is thought to be partially responsible for the lack of  
9  
10 354 reliable biomarkers in psychiatry despite intense research in neuroimaging <sup>77</sup>. Indeed, region-of-  
11  
12 355 interest studies are directed towards regions that can be easily anatomically delimited or regions of  
13  
14 356 theoretical importance, which intrinsically depend on results from previous studies, thereby  
15  
16 357 inflating the risk of confirmation bias. We completed the initial whole-brain approach with the  
17  
18 358 individual analysis of two VOIs (i.e. ventricles and hippocampus) that are commonly implicated  
19  
20 359 among structural findings in psychosis but are the best assessed individually, using volumetric  
21  
22 360 information from the subcortical segmentation in Freesurfer. Instead of running additional region-  
23  
24 361 of-interest analyses in the hypothesized fronto-temporal and limbic regions, we examined the group  
25  
26 362 difference using  $p < 0.001$  uncorrected, at the voxel or the vertex level for both the VBM and SBM  
27  
28 363 analyses respectively. In the context of the literature, neither the direction of the trend (i.e.,  
29  
30 364 increased GMV or CT), nor the location of the clusters (i.e. precentral gyrus, frontal pole) advocate  
31  
32 365 in favor of true differences between ARMS and HC. For inclusion of these data in a meta-analysis,  
33  
34 366 GMV, WMV or CT for a specific region are available on request to the corresponding author (J.Z).

35  
36  
37  
38  
39 367 Our results might also be limited by the cross-sectional design of the study. Cannon and  
40  
41 368 colleagues have recently reported greater GM loss over time in several frontal areas of ARMS-T  
42  
43 369 when compared to ARMS-NT or HC, although they observed no CT differences between all 3  
44  
45 370 groups when compared cross-sectionally at baseline <sup>18</sup>.

46  
47  
48 371 Last, our analysis was limited to anatomical changes in gray and white matter segments. Two  
49  
50 372 functional MRI studies in the same ARMS sample have previously reported alterations in task-  
51  
52 373 based activations <sup>78</sup> as well as abnormalities in functional-connectivity at rest <sup>79</sup> when compared to  
53  
54 374 HC. This suggests that, in our sample, (1) there might be very little structural change in ARMS or  
55  
56 375 (2) VBM and SBM analyses may not be sensitive to detect subtle structural differences. Functional  
57  
58  
59  
60

1  
2 376 or diffusion MRI studies might reveal more insights on the pathophysiology changes in youths at  
3  
4 377 high clinical risk for psychosis.

5  
6 378

7  
8 379 **Conclusion**

9  
10 380 Taken together, this comprehensive cross-sectional analysis of regional volumes and cortical  
11  
12 381 thickness was conducted in a relatively large sample of ARMS subjects, mainly free of possibly  
13  
14  
15 382 important confounds including antipsychotic medication and substance abuse. Only few whole  
16  
17 383 brain studies have examined brain structural changes in an ARMS sample of comparable size,  
18  
19 384 particularly in Asian populations<sup>80</sup>. We found no evidence of regional GMV, WMV or CT  
20  
21 385 differences between ARMS and HC, ARMS-T and HC or ARMS-T and ARMS-NT at baseline.  
22  
23 386 The small number of ARMS transitioning to psychosis and the absence of longitudinal analysis of  
24  
25 387 brain changes over-time are clear limitations, especially in light of recent findings suggesting  
26  
27 388 progressive structural changes in ARMS despite the absence of baseline differences with HC<sup>18</sup>.  
28  
29 389 Nevertheless, our negative findings suggest that there may be no dramatic alterations of regional  
30  
31 390 brain volumes or cortical thickness in ARMS when the incidence of possible confounds is limited.

3  
4 610 **Table 1. Demographic, clinical and anatomical characteristics of participants**

5  
6 611 APS, attenuated psychotic symptoms; BAI, Beck anxiety inventory; BLIPS, brief limited  
7  
8 612 intermittent psychotic symptoms; CAARMS, comprehensive assessment of at-risk mental  
9  
10 613 states; CDSS, Calgary depression scale for schizophrenia; GRD, genetic risk and  
11  
12 614 deterioration syndrome; GM, grey matter; ICV, intracranial volume; PSLE, primary school  
13  
14 615 leaving examination; SBM, surface-based morphometry; SUD, substance use disorder;  
15  
16 616 VBM, voxel-based morphometry; WM, white matter; Percentages were rounded to the  
17  
18 617 nearest integer. All ARMS and control subjects belong to the three major ethnicities in  
19  
20 618 Singapore (Chinese, Malay and Indian), except two ARMS (Javanese and Eurasian) and two  
21  
22 619 controls (Javanese and Israeli).
