ABSTRACT. We present an update of the ‘key points’ from the Antarctic Climate Change and the Environment (ACCE) report that was published by the Scientific Committee on Antarctic Research (SCAR) in 2009. We summarize subsequent advances in knowledge of how the climates of the Antarctic and Southern Ocean have changed in the past, how they might change in the future, and examine the associated impacts on the marine and terrestrial biota. We also incorporate relevant material presented by SCAR to the Antarctic Treaty Consultative Meetings, and make use of emerging results that will form part of the Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report.

Introduction

Between 2006 and 2008 the Scientific Committee on Antarctic Research (SCAR) undertook a major review of the state and current understanding of Antarctic and Southern Ocean climate science. The study spanned change from Deep Time, through the Holocene and the instrumental period, to predictions of possible change over the next century under a range of greenhouse gas emission scenarios. The project Antarctic Climate Change and the Environment (ACCE), was first discussed by the SCAR Executive Committee at its meeting in Bremen in July 2004, which agreed that SCAR should consider carrying out an Antarctic climate assessment as a counterpart to the Arctic Climate Impact Assessment to contribute to the Antarctic Treaty Consultative Meeting (ATCM) and the Intergovernmental Panel on Climate Change (IPCC) deliberations. The plan for the assessment was approved by the Executive Committee at its meeting in Sofia, Bulgaria in July 2005 and formally approved by SCAR Delegates in Hobart, Australia in July 2006. The form and scope of the project was defined at a SCAR cross-Standing Scientific Group meeting in November 2006 with the writing and editing taking place over the following two years. The project was coordinated by a nine-person steering committee with a total of 97 scientists from 12 countries eventually contributing to the writing. A draft of the report was distributed and made accessible for comment to the international Antarctic science community and beyond, leading to further revision during 2008 and 2009. The resulting 526-page report (Turner et al., 2009a) was launched at the Science Media Centre in the Royal Institution, London on 30 November 2009. At the same time, a summary review of the Report was published in the scientific journal *Antarctic Science* (Convey et al. 2009).

Hardcopy versions of the report were distributed to all the contributors, the 53 national representatives at the UN Framework Convention on Climate Change meeting in Copenhagen, five UN agencies, all 35 SCAR National Delegates and several polar libraries. An online PDF version of the report is available to download without cost from the SCAR web site (<http://www.scar.org/publications/occasionals/acce.html>) or hardcopies are available to purchase from <http://www.scar.org/publications/>.

During the preparation of the ACCE report it became apparent that many areas of Antarctic science were advancing at a rapid pace and the editors strove to add the latest results up until the time of printing of the volume. However, it was also clear that while a large part of the ACCE report would have lasting value as background material, it would be necessary to update the report on a regular basis as new research results emerged. Short information papers describing recent advances in Antarctic climate change and its possible impacts on biota were presented to the ATCM in May 2010 (Punta del Este, Uruguay), June 2011 (Buenos Aires, Argentina) and June 2012 (Hobart, Australia) – available from <http://www.scar.org/publications/occasionals/acce.html>. While these updates provided selected research highlights, a more in-depth update on climate-related advances was still required. Here we update the ‘key points’ from the 2009 ACCE report. Whereas the original key points were an executive summary of the full ACCE report and therefore did not incorporate citations, the present paper is intended as a standalone report and includes a selection of key, mostly recent, references. The 2009 ACCE report should be consulted for comprehensive reference to the previous literature.

Many of the key points from the original ACCE report are still valid and have been left largely unchanged if the science has not advanced significantly. Some areas of science have developed rapidly since 2009 and the entries have been rewritten completely to reflect the progress.

The Antarctic climate system

1. The Antarctic climate system varies on timescales from orbital, to millennial to sub-annual and is closely coupled to other parts of the global climate system. The ACCE report discussed these variations from the perspective of the geological record and the recent historical period of instrumental data (approximately the last 50 years), discussed the consequences for the biosphere, and documented the latest numerical model projections of changes into the future, taking into account human influence due to the release of greenhouse gases and chlorofluorocarbons to the atmosphere. The report highlighted the large uncertainties in the vulnerability of the West Antarctic Ice Sheet (WAIS). The profound impact of the ozone hole on the Antarctic environment over the last 30 years, shielding the continent from much of the effect of global warming was noted. This effect is not expected to persist. Over the next century ozone concentrations above the Antarctic are expected to recover and, if greenhouse gas atmospheric concentrations continue to increase at the present rate, temperatures across the continent are projected to increase by several degrees and sea ice will be reduced by about one third.

The Geological Dimension (Deep Time)

2. Studying the history of climate and the environment provides a context for understanding present day climate and environmental changes. It allows researchers to determine the processes that led to the development of the present interglacial period and to define

the ranges of natural climate and environmental variability on timescales from decades to millennia over the past million years, and at coarser resolution across deep geological timescales. Knowing this natural variability, researchers can identify when present day changes exceed the natural range. Palaeorecords show that change is normal, and that non-linear abrupt climate changes can occur.

3. Concentrations of the greenhouse gas CO₂ in the atmosphere have ranged from ~3000 ppm (parts per million) in the Early Cretaceous 130 million years ago (Ma) to ~1000 ppm in the Late Cretaceous (at 70 Ma) and Early Cenozoic (at 45 Ma), leading to global temperatures 6° or 7°C warmer than present. These high CO₂ levels were products of Earth's biogeochemical cycles. During these times there was little or no ice on land. In the pre-industrial period of the early 19th century the concentration of CO₂ in the atmosphere was about 280 ppm. The CO₂-rich, ice-free, warmer earlier periods created what is now referred to as a 'Greenhouse World'. The later parts of the Tertiary Period to the present: characterized by low CO₂, abundant ice and cool temperatures, created what is referred to as an 'Icehouse World'.
4. The first continental-scale ice sheets formed on Antarctica around 34 Ma, most likely in response to a decline in atmospheric CO₂ levels caused by a combination of reduced CO₂ out-gassing from mid-ocean ridges and volcanoes and increased carbon burial stimulated by the erosion of newly rising mountains – the Himalayas. This decline resulted in a fall in global temperatures to around 4°C higher than today. At a maximum these early ice sheets reached the edge of the Antarctic continent, but were most likely warmer and thinner than today's ice sheets. Further sharp cooling took place at ~14 Ma, probably accelerated by the growing physical and thermal isolation of Antarctica as other continents drifted away from it and the Antarctic Circumpolar Current (ACC) developed. At that time the ice sheet thickened to more or less its

modern configuration. Alkenone-based CO₂ reconstructions, from both high- and low-latitude sites in the Atlantic and Southern Oceans show that CO₂ levels declined precipitously just prior to and during the onset of glaciations, confirming that CO₂ played a dominant role in the inception of Antarctic glaciations (Pagani et al., 2011). During the Pliocene, 5-3 Ma, mean global temperatures were 2-3°C above pre-industrial values, CO₂ values may have reached ~400 ppm, and sea levels were 15-25 m above today's. There is evidence for Pliocene WAIS collapse from the ANtarctic geological DRILLing (ANDRILL) project geological records, a feature also simulated by models (Pollard and DeConto, 2009), in response to this warming.

5. The earliest cold-climate marine fauna in the Southern Ocean is thought to date from the latest Eocene-Oligocene (c. 35 Ma). The establishment of the oceanic Polar Front created a barrier for migration of marine organisms between cold Antarctic and warmer waters at lower latitudes. This promoted adaptive evolution of the current Antarctic marine biota, and led to an overall moderate species diversity and regionally high biomass. The evolution of antifreeze proteins and the loss of haemoglobin in the fish group of the Notothenioidei is a prominent example of evolution coping with low thermal tolerance (Beers and Sidell, 2011) and of diversification (Matschiner et al., 2011). The development of sea ice made the success of krill possible. Krill have a high potential to disperse and show regional genetic variation and physiological plasticity similar to that of icefish. Krill shaped the trophic structure of the Antarctic open ocean ecosystem and served as a major food source for globally occurring seabirds and whales. Despite the Polar Front acting generally as a barrier to the dispersal of invertebrates and fish, some deep-sea and shelf inhabiting species still exchanged with northerly adjacent areas (Gutt et al., 2010). During the late Quaternary there is evidence from Bryozoan communities of a shallow seaway

opening up between the Weddell and Ross Sea (Barnes and Hillenbrand, 2010). ANDRILL results confirm the likely breakup of the WAIS at times during the Quaternary.

6. In an analogous fashion, circumpolar atmospheric circulation patterns isolated terrestrial habitats from potential sources of colonists from lower latitudes. In contrast with the marine environment, the combination of continental scale ice sheet formation and advance, and extreme environmental conditions, led to large-scale decline of pre-existing biota, and to evolutionary radiation amongst survivors. Fossil evidence shows the change from species associated with arid sub-tropical climates of Gondwanaland to cool temperate rainforest and then cold tundra when Antarctica was isolated by the opening of the Drake Passage and by the separation from Australia along the Tasman Rise. Most of these species are now extinct on the continent but, recent molecular, phylogenetic and fossil evidence suggests that some species groups have adapted to the environmental changes including chironomid flies, mites, copepods, springtails, nematodes, diatoms, green algae (De Wever et al., 2009), cyanobacteria, and heterotrophic bacteria (Peeters et al., 2011). Many of these species are endemic to the continent.

The Last Million Years

7. The long periods of cold of the Pleistocene glaciation (post 2.6 Ma) were subject to cycles of warming and cooling. Periodicities of 20,000, 41,000 and 100,000 years calculated from sediment and ice cores show that the cycles were paced by variations in the Earth's tilt, and its orbit around the Sun. These changes in incoming solar energy

initiated feedback loops whereby small changes in temperature brought about larger changes in global atmospheric CO₂ and methane, which enhanced the temperature rises by positive feedback. The climates of the two hemispheres were physically linked, warming or cooling the planet as a whole through the greenhouse effect. These processes led periodically to the development of short warm interglacial periods like that of the last 10,000 years. Over the past 450,000 years warm interglacial periods recurred at intervals of around 100,000 years. Prior to that, interglacials were less warm and before a million years ago they recurred at intervals of close to 40,000 years.

8. Paleoclimate data, including Antarctic ice core records from glacial cycles over the last 800,000 years, show that CO₂ and mean global temperature values ranged globally from 180 ppm and 10°C in glacial periods to 280 ppm and 15°C in interglacial periods. In Antarctica, the pre-industrial cold periods were on average 9°C colder than interglacials. Ice sheets in Antarctica and on the northern continents expanded in glacial periods, with sea level dropping by 120 m on average. Ice core data suggest a major control by the Southern Ocean on glacial-interglacial variations in atmospheric CO₂ concentration, due to changes in CO₂ solubility (less CO₂ dissolves in warm seas), the efficiency of the 'biological pump' (which stored CO₂ in deep ocean waters during glacials) and changes in ocean circulation (the thermohaline conveyor belt sped up during interglacials, pushing more CO₂-rich deep water to the surface), and in sea ice cover (the melting of sea ice during interglacials exposed upwelling deep water rich in CO₂ to the atmosphere, encouraging ocean-atmosphere exchange).
9. Ice cores from Antarctica show that some interglacials in the last 400,000 years reached temperatures up to 5°C higher than they are today. Sea level was also higher in some of these interglacials, with possible extremes of 9 m higher in the last interglacial.

Methane ranged between about 350 and 720 ppb. The Last Interglacial (around 130,000 years BP (before present)), when the temperature in Antarctica may have been as much as 5°C higher than in the pre-industrial period is of particular interest. This warm Antarctic period coincided with the end of Northern Hemisphere deglaciation and preceded warmer than present Arctic conditions (2-5°C warmer than present day). The documentation of 6.6 m higher than present sea level during this time period (Kopp et al., 2009) points to significant loss of Greenland and Antarctic ice. While climate models are able to capture the patterns of the orbital-driven warming of the Arctic, they cannot represent the Antarctic warming during this interval unless they incorporate Greenland melt and possibly partial loss of the WAIS.

10. Antarctic ice cores reveal regional differences in the patterns of Antarctic millennial variability, especially between the Atlantic and Indo-Pacific sectors. Precise synchronization of Greenland and Antarctic records shows that each abrupt climate event of the Northern Hemisphere has an Antarctic counterpart. However, warming in Antarctica precedes warming in Greenland, and Antarctic cooling precedes Greenland cooling, suggesting a bipolar seesaw pattern consistent with the theoretical consequences of reorganizations in the Atlantic Meridional Overturning Circulation (AMOC). Under this scenario, changes in the northward heat flux along the length of the Atlantic have impacts such that the Southern Hemisphere warms while the North Atlantic is cold, and cools when the North Atlantic is warm.
11. Diatom data from sediment cores show that at the last glacial maximum (LGM), about 21,000 years BP, Antarctic sea ice was double its current extent in winter and also increased in extent in summer in at least some ocean sectors. In the Scotia Sea there is evidence that winter sea ice reached its maximum extent between 24,100 and 23,500 years BP, and summer sea ice between 30,800 and 23,500 years BP. This predates the

LGM (Collins et al., In Press), and supports some models that show retreat of this ice before the LGM as a potential trigger for global deglaciation (Allen et al., 2011). Related sea surface temperature calculations show that both the Polar Front and the sub-Antarctic Front shifted to the north during the LGM by between 2° and 10° in latitude from their present locations.

12. The Southern Ocean is almost certainly the main locus of changes that led to the large increase in atmospheric CO₂ concentration between the LGM and the Holocene (Shakun and Carlson, 2010). The cause is likely to have been a combination of changes in the strength of physical and biogeochemical processes. One recent study (Tschumi et al., 2011) shows Southern Ocean deep waters were stratified and depleted in radiocarbon during the last glacial period and through the early deglaciation up to ~14.6 ka BP. Afterwards deep ocean carbon was transferred to the surface and atmosphere via a Southern Ocean ventilation event consistent with the re-starting of the Meridional Overturning Circulation (MOC). This partially explains the elevation of atmospheric CO₂ values between glacial and interglacial periods (Burke and Robinson, 2012).
13. The expansion and contraction of Antarctica's ice sheets undoubtedly led to the local extinction of some biological communities on the Antarctic continent during glacial periods. The resulting present-day biodiversity consists of species that either survived the glacial maxima in refugia, then recolonized deglaciated areas, or arrived through inter- and post-glacial dispersal from lower latitude lands that remained ice free, or are present through a combination of both mechanisms (McGaughan et al., 2010).
14. Continuous evolutionary development during glacial times in refugia, in combination with low extinction rates, is assumed to be a major driving force explaining the relatively high biodiversity of benthic (bottom-dwelling) marine organisms.

Expansions and contractions of the sea ice had an impact on mammal and seabird distributions and general ecosystem functioning. These various expansions and contractions continued into the Holocene.

The Holocene

15. The transition from the LGM to the present interglacial period (the Holocene, beginning around 12,000 years BP) was the last major global climate change event. Ice core and geological evidence from land in Antarctica shows a marked warming period in the Holocene, between 11,500 – 9,000 years BP; this is a period of maximum insolation for the Antarctic determined from astronomical calculations. Some marine records show evidence of a marine optimum between about 7,000 - 3,000 years BP, and many terrestrial records show evidence of an optimum between 4,000 - 2,000 years BP. These warm periods were likely to have raised temperatures by no more than around 0.5-1°C.
16. The ice core record indicates changes in atmospheric circulation in the Antarctic. They suggest strengthening of the Southern Hemisphere westerlies at 6,000 years BP followed by abrupt weakening at 5,400-5,200 years BP. They also suggest intensification of the westerlies and the Amundsen Sea Low pressure cell at around 1,200 years BP (Mayewski et al., 2009).
17. There is no evidence in Antarctica for a precise equivalent to the Northern Hemisphere Medieval Warm Period (MWP), but some periods of the last 1000 years were likely as warm or even warmer than the late 20th century (Goosse et al., 2012). There is also some evidence for a cool event equivalent in time to the Northern Hemisphere's Little

Ice Age (LIA) in some of the ice core data (Bertler et al., 2011). Ice core records suggest that the LIA is the most prominent event of the last ~5,000 years in Antarctica (Mayewski et al., 2004).

18. Associations between changes in solar energy output and climate have been debated for many years. Satellite observations have demonstrated that the association is not a consequence of simple heating of the upper atmosphere. However, associations have been demonstrated between changes in solar energy output, at least for solar cycle duration, and in ozone concentration in the lower stratosphere. Ice core records suggest a link between solar energy output changes and changes in atmospheric circulation through changes in ozone concentration. It is intriguing to consider that stratospheric ozone has played an important role in both naturally varying changes in atmospheric circulation and the recent more dramatic shifts in atmospheric circulation associated with the anthropogenic Antarctic ozone hole (Mayewski et al., 2006).
19. The main biological changes occurring during the Holocene were the recolonisation of habitats as the ice sheet retreated, both by species that had survived the glaciation on the continent and continental shelf and by others originating from lower latitude landmasses. Species assemblages and distributions have also responded to periods of positive and negative temperature changes in the Holocene. In particular, those species with narrow ecological ranges or sensitivity to physical factors such as the changing extent of sea ice (penguins and seals). These responses provide insight for predicting changes under future warming scenarios.

Changes during the Instrumental Period

20. The instrumental period is considered to have begun in the Antarctic with the International Geophysical Year of 1957-58. Here we discuss key changes in the atmosphere, ice and ocean systems, and the biosphere since that time.

The large scale circulation of the atmosphere

21. The major mode of variability in the atmospheric circulation of the high southern latitudes is the Southern Hemisphere Annular Mode (SAM). This is a circumpolar pattern of atmospheric mass displacement in which the intensity and location of the gradient of air pressure between mid-latitudes (higher pressure) and the Antarctic coast (lower pressure) changes in a non-periodic way over a wide range of time scales from days to years. Over the past 50 years the SAM became more positive (stronger circumpolar westerly winds) in the austral summer and autumn, as pressure dropped around the coast of the Antarctic and increased at mid-latitudes (Thompson et al., 2011 and references therein). Since the late 1970s the strength of the westerly winds over the Southern Ocean has increased by 15-20% (Korhonen et al., 2010; Turner and Marshall, 2011) and has resulted in a poleward migration of the westerlies by 1-2° of latitude. The change in the SAM has led to a decrease in the annual and seasonal numbers of cyclones south of 40°S. There are now fewer but more intense cyclones in the Antarctic coastal zone between 60 and 70°S, except in the Amundsen-Bellinghousen Sea region (Simmonds et al., 2003). The combination of the stronger westerly winds around the continent, with the off-pole displacement of Antarctica, has led to a deepening of the Amundsen Sea Low, with consequent effects on temperature and sea ice in the coastal region of West Antarctica. These increased wind speeds and

the decreasing ozone concentration have been linked with decreased growth rates of plants (Clarke et al., 2012) and biodiversity changes in lakes (Hodgson et al., 2006) in East Antarctica. From ice core records it appears that intensification of the westerlies and the Amundsen Sea Low started as early as the late 1800s, but in recent decades the intensification associated with ozone depletion is more pronounced (Dixon et al., 2012).

22. The observed trend in the SAM has been largest during the austral summer. It is believed to be driven primarily by the development of the Antarctic ozone hole (Thompson et al., 2011 and references therein). Evidence that increased greenhouse gases have played a role is conflicting (Treguier et al., 2010). The ozone hole forms in the austral spring; at that time of year the loss of stratospheric ozone cools the Antarctic stratosphere, so increasing the strength of the polar vortex – a large high altitude cyclonic circulation that forms in winter in the stratosphere above the Southern Ocean around Antarctica. These anomalies precede similarly signed anomalies in the tropospheric circulation during summer, i.e. a strengthening of the Southern Hemisphere circumpolar winds from the lower stratosphere to the surface due to the ozone hole.

23. In recent decades there have been more frequent and more intense El Niño events. During some of them a signal of the El Niño cycle can be seen in the Antarctic. Ice core records may preserve evidence of El Niño-Southern Oscillation (ENSO) signals as far south as the South Pole (Meyerson et al., 2002). There is no evidence that this trend has affected long term climate trends in the Antarctic. In addition, atmospheric circulation and temperature reconstructed from ice cores show large inter-annual to decadal variability, with the dominant pattern being anti-phase anomalies between the

continent and both West Antarctica and the Antarctic Peninsula, which is associated with the SAM during the recent period of observations.

Atmospheric temperatures

24. Surface temperature trends show significant warming across the Antarctic Peninsula and to a lesser extent the rest of West Antarctica since the early 1950s, with little change across the rest of the continent (Turner et al., 2005). The largest warming trends have been on the western and northern parts of the Antarctic Peninsula. There Faraday/Vernadsky Station, at 65.4° S on the western Peninsula, has experienced the largest statistically significant (<5% level) trend of +0.54° C per decade for the period 1951 – 2011; the warming has taken the form of a reduction in the number of extreme cold winters at the Peninsula (Turner et al., 2012). The longest temperature record at high southern latitudes is from Orcadas on Laurie Island, South Orkney Islands, and it shows a warming of +0.21° C per decade since 1904. The western Peninsula warming has been largest during the winter, with temperatures at Faraday/Vernadsky during that season increasing by +1.01° C per decade from 1950 - 2011. There is a high correlation during the winter between sea ice extent a few hundred kilometers from the station and surface temperatures (Turner et al., 2012), suggesting more sea ice during the 1950s - 1960s and a reduction since then. Over 2000 – 2011 there was a slight drop in the annual mean temperature at stations on the Antarctic Peninsula north of Faraday/Vernadsky (Blunden and Arndt, 2012).
25. Temperatures on the eastern side of the Antarctic Peninsula have risen most during the summer and autumn (at +0.39° C per decade from 1946 - 2011 at Esperanza), linked to

the strengthening of the westerlies that took place as the SAM shifted into its positive phase, primarily as a result of the ozone hole (Thompson et al., 2011 and references therein). Stronger westerly winds now bring warm, maritime air masses across the Peninsula to the low-lying ice shelves on the eastern side with the Foehn effect adding to the warming of the air masses coming over the Peninsula (Marshall et al., 2006).

26. Based on data from satellites and automated weather stations, it has been suggested that West Antarctica has warmed by about 0.1°C per decade since the late 1950s, especially in winter and spring (Steig et al., 2009). Other analyses put the warming at slightly less than this (O'Donnell et al., 2011). Ice core data from the Siple Dome suggest that this warming began around 1800. Recent warming across continental West Antarctica has been linked to sea surface temperature changes in the tropical Pacific. Over the past 30 years, anomalous sea surface temperatures in the central tropical Pacific have generated an atmospheric Rossby wave response that influences atmospheric circulation over the Amundsen Sea, causing increased advection of warm air to the Antarctic continent. General circulation model experiments also link the central tropical Pacific with the observed high latitude response. By affecting the atmospheric circulation at high southern latitudes, increasing tropical sea surface temperatures may account for West Antarctic warming through most of the Twentieth Century (Ding et al., 2011).
27. On the plateau, Amundsen-Scott Station at the South Pole shows a statistically significant cooling in recent decades, interpreted as due to fewer warm maritime air masses penetrating into the interior of the continent. This could also be a manifestation of the low-pressure anomaly that now propagates downward from the ozone hole.
28. Temperatures reconstructed from ice cores show large inter-annual to decadal variability, with one reconstruction suggesting that Antarctic temperatures increased on average

by about 0.2°C since the late 19th Century (Schneider et al., 2006). Three ice borehole temperature time series from the Peninsula, West Antarctica and East Antarctica all show a significant warming in recent decades. The East Antarctic data (Muto et al., 2011) covered the last 20-50 years on the Dronning Maud Land divide, a region without any other long-term records. Warming of $0.1\text{-}0.2\text{ C/decade}$ was indicated by both Monte Carlo and inverse methods. The results from the Peninsula (Zagorodnov et al., 2012) match well with other ice core chemistry and borehole records from the region, showing a low in mean annual temperature around 1930 then increasing at $\sim 0.33\text{ C/decade}$ until about 1995, and then a slight flattening or cooling of $\sim 0.5\text{ C}$ in the most recent decade. The West Antarctica data (Orsi et al., 2012) show that cool conditions prevailed on the WAIS during the Little Ice age period, and that warming began around 1800 and continued through the past 100 years. A sharp increase in the rate of warming in the past 20 years, to $\sim 0.7\text{C/decade}$, is indicated by the data.

29. Antarctic radiosonde temperature profiles show that the troposphere has warmed at 5 km above sea level, and that the stratosphere above it has cooled over the last 30 years. This pattern would be expected from increasing greenhouse gases. The tropospheric warming in winter is the largest on Earth at this level (Turner et al., 2006). It may, in part, be a result of the insulating effect of greater amounts of polar stratospheric clouds during the winter (Lachlan-Cope et al., 2009).
30. Over Antarctica, there has been long-term stratospheric cooling of annual mean temperatures of $\sim 0.5^{\circ}\text{C}$ per decade (between 1979 and 2007) and there are tentative indications of $\sim 1^{\circ}\text{C}$ per decade cooling in the mesosphere ($\sim 87\text{ km}$). Various data series show a mean solar cycle variation (solar maximum minus solar minimum) in temperature in the stratosphere of between 0.1°C and 1°C , and in the mesosphere at $\sim 87\text{ km}$ of typically between 3°C and 6°C . There is growing evidence (Seppälä et al.,

2009) that solar variability has some influence on Antarctic regional climate, though the chain of causality has yet to be established and the effects fully quantified. To extract the signal with a high level of confidence, long well-populated datasets are required throughout the atmosphere and these have been limited in Antarctica due to the sparse instrumentation and shortness of the records. Solar UV variability brings about changes in stratospheric temperature and ozone, which, through subsequent changes in planetary wave motion and the SAM, can alter stratosphere-troposphere coupling, and hence tropospheric wind variability. Uniquely in Antarctica, because of the dynamic stability of the southern polar vortex, solar wind variability strongly influences the amount of NO_x entering the stratosphere from above.

31. Antarctic observations of hydroxyl airglow in the mesopause region (87 km altitude) show annual average cooling trends of 1-2°C per decade (over the last 2 decades) with a strong seasonal variation (French and Klekociuk, 2011). Maximum cooling rates of around 4°C per decade occur in August-September at the time of the ozone depletion, with little or no trend over the winter months. These long-term trends are superimposed on a solar cycle response of 4-5°C per 100 solar flux units. This response appears to be stronger over the Antarctic than at low latitudes or in the Northern Hemisphere (Beig et al., 2008).
32. An updated set of time series of derived aerosol optical depth (AOD) from a number of Antarctic stations has been analyzed to determine the long-term variations. The Antarctic data-set comprises sun-photometer measurements made at Mirny (1982 - 2009), Neumayer (1991 - 2004), Terra Nova Bay (1987 - 2005), and at South Pole (1977 - 2010). The long-term variation in Antarctic AOD was estimated to be stable, within $\pm 0.10\%$ per year, at the three coastal sites. At South Pole there has been a small

decrease, possibly due to the formation of thin stratospheric layers of ageing volcanic particles (Tomasi et al., 2012).

Snowfall

33. On average, about 7 mm global sea level equivalent (~2,500 Gt ice equivalent mass) falls as snow on Antarctica each year, but there has been no statistically significant change since 1957 (Monaghan et al., 2006). Snowfall trends vary from region to region, with the greatest accumulation in the Antarctic Peninsula and coastal West Antarctica, adjacent to the Amundsen Sea Low, which advects warm, moist air from lower latitudes. Integrated over the entire ice sheet, snowfall shows modest interannual variability (standard deviation of 114 Gt per yr), yet a pronounced seasonal cycle (standard deviation of about 30 Gt per month). Snowfall has increased on the western side of the Peninsula, where it has been linked to decreases in Adélie penguin populations, which prefer snow-free nesting habitat and nest earlier than Gentoo or Chinstrap penguins when there is now an increased likelihood of snow burying nests. There is little evidence of broad regional increases in East Antarctic accumulation.
34. Recent research has highlighted the interaction between the wind field and snowfall, and the presence of large 'hiatus' areas in East Antarctica (Arcone et al., In Press). Such areas combine to cover up to 10% of the plateau surface above 1500 m, and result in a net reduction of the estimate of true current accumulation of East Antarctica (from models or from interpolated observations) of 40-80 Gt. This has significant implications for mass balance studies.

35. The time-series of temperature and snow accumulation rates reconstructed from the data from eight snow pits and four shallow cores drilled near Vostok Station show that the regional climate is dominated by the quasi-periodic oscillations of these parameters with a period of 40-50 years. Average accumulation rate varied from 1.2 to 3.0 g/cm² with an average of 2.01 g/cm². Temperature varied from -56.5°C to -54.0°C. The cyclical character of the changes in the region during the last three centuries is confirmed by the temperature data in the upper 100 m of ice as well as by instrumental measurements of air temperature for the recent decades (Ekaykin et al., 2011). The zonal and meridional components of the circulation to a large extent dictate the temperature and precipitation anomalies. In the early 1970s the sign of the relationship between many climatic parameters changed, which is likely related to the rearrangement of the climate system of the Southern Hemisphere. The data suggest that during the past 350 years such events have happened at least five times. (Kozachek et al., 2011).

The Antarctic ozone hole

36. Stratospheric ozone amounts began to decline in the 1970s, following widespread releases of chlorofluorocarbons (CFCs) and halons into the atmosphere that destroyed virtually all ozone between heights of 14 and 22 km over Antarctica each spring and early summer. Owing to the success of the Montreal Protocol, the amounts of ozone-depleting substances in the stratosphere are now decreasing by about 1% per year. As a result the size and depth of the ozone hole have stabilized, but are not yet decreasing. The interannual variability of the ozone hole remains largely controlled by

meteorological factors in the stratosphere. Model calculations suggest that the decline in Antarctic ozone is linked to marked changes in surface climate. See Thompson et al., 2011 and references therein for details).

Terrestrial biology

37. A meta-analysis of the response of polar plants to UV-B radiation under field conditions confirms that elevated UV-B exposure leads to increasing concentrations of UV-B protective compounds in photosynthetic tissues, reduced above-ground biomass and plant height and increased DNA damage (Newsham and Robinson, 2009). The sensitivity of plant growth to ozone-induced variations in UV-B radiation indicates an approximate 1% reduction in growth for each 3% increase in weighted UV-B irradiance (Newsham and Robinson, 2009). Based on this analysis, Ballare et al. (2011) estimated that, for areas subject to substantial ozone depletion, e.g. the southern tip of South America (at 55° S) where ozone depletion has led to a 20% increase in the summertime levels of UV-B radiation, the resulting decrease in plant growth rate over the past three decades would be about 6%.
38. The clearest example of Antarctic terrestrial organisms responding to climate change is given by the two native flowering plants (*Deschampsia antarctica* and *Colobanthus quitensis*) in the maritime Antarctic, which have increased in abundance at some sites. Warming encourages the growth and spreading of established plants, increased seed set and increased establishment of seedlings. Changes in temperature and precipitation have also increased biological production in lakes and altered species assemblages, mainly due to decreases in the duration and extent of lake ice cover. Some lakes have

become more saline due to drier conditions. Shorter term (decadal) decreasing temperature in the Dry Valleys reduced primary production in lakes and the number of soil invertebrates (Doran et al., 2002). These ecosystems might be especially sensitive to climate change and respond differently at different temporal scales (Nielsen et al., 2011). As noted earlier in point 21, ozone depletion and increasing wind speeds have also impacted the terrestrial biota.

The terrestrial and marine cryosphere

39. Ice shelves along the Antarctic Peninsula have changed rapidly in recent decades, with episodes of retreat, breakup and collapse occurring on both side of the Peninsula. The overall reduction in total ice shelf area during the last five decades has been estimated to be over 28,000 km² (Cook and Vaughan, 2010). Loss of ice on the eastern side results predominantly from warm air being brought over the Peninsula by the stronger westerlies forced by changes in the SAM and, ultimately, driven by the development of the ozone hole. Ice shelf thinning has been attributed both to surface and sub-surface melting (Scambos et al., 2000; Pritchard et al., 2012). In the northern Antarctic Peninsula surface warming began approximately 600 years ago (Sterken et al. 2012), so the ice shelves were preconditioned for collapse as the rate of warming intensified during the last 100 years (Mulvaney et al. 2012). Ice-shelf collapse is thought to result from hydro-fracture of water-filled crevasses combined with changes in firn density and ice thickness as a result of local changes in surface mass balance and rates of basal melt. Retreat of ice shelves in the Antarctic during the instrumental period appears to be synchronous with those in the Arctic (Hodgson, 2011). Removal

of ice shelves has led to speed-up of upstream glacier flow from inland due to reduction in buttressing forces.

40. Some formerly snow- and ice-covered sub-Antarctic islands are now increasingly snow-free during the summer. Brown Glacier on Heard Island lost 29% of its surface area between 1947 and 2004, causing the formation of several lagoons. On South Georgia, 97% percent of 103 coastal glaciers surveyed from the 1950s to the present have retreated and the average rate of retreat has increased from 8Ma^{-1} in the 1950s to 35Ma^{-1} at present (Cook et al. 2010). Further south in the South Shetland Islands, the ice-covered area of King George Island decreased by 1.6% during 2000-2008 (Ruckamp et al., 2011), a rate of loss similar to that of the period 1956-1995, when the ice-covered area decreased by 7%.

41. Of the 244 marine-terminating glaciers that drain the northern sector of the Antarctic Peninsula ice cap, 212 (87%) showed overall retreat since 1953. The remaining 32 glaciers (13%) have shown small advances. Studies analyzing both marine-terminating and land-terminating glaciers in the region also show an overall trend of retreating ice fronts. There is a range of variations throughout the study area including stationary ice fronts on the northwestern coast of the Antarctic Peninsula (Rau et al., 2004). The rates of recession, however, seem to be declining. In a study of 194 glaciers on Trinity Peninsula, Vega Island and James Ross Island, Davies et al. (2012) show that, over 1988-2001, 90% of glaciers receded, while for 2001-2009, 79% receded. Glaciers on the western side of Trinity Peninsula retreated relatively little. The total glaciated area in the northern Antarctic Peninsula declined by 11.1% during 1988-2001 and by 3.3% during 2001-2009. The tidewater glaciers on the Eastern Trinity Peninsula, and the land-terminating glaciers on James Ross Island also retreated fastest in the period 1988-2001. Only the large tidewater glaciers on James

Ross Island are declining in areal extent at faster rates after 2001. A recent study of the mass balance of the different sectors of the Antarctic based on the various forms of satellite data (Shepherd et al., 2012) found that over 1992 – 2011 the mass of the Peninsula changed by $-20 \pm 14 \text{ Gt year}^{-1}$.

42. The Amundsen Sea sector of West Antarctica is the most rapidly changing region of the Antarctic ice sheet (Jenkins et al., 2010). The grounding line at Pine Island has retreated and the Pine Island glacier is now moving at speeds 60% higher than in the 1970s. The Thwaites Glacier and four other glaciers in this sector show accelerated thinning. Smith Glacier has increased flow speed 83% since 1992. Pine Island and adjacent glacier systems are currently more than 40% out of balance, discharging $280 \pm 9 \text{ Gt}$ of ice per year, while they receive only $177 \pm 25 \text{ Gt}$ per year of new snowfall. The current rate of mass loss from the Amundsen Sea embayment ranges from 50 to 137 Gt per year. This loss is equivalent to the current rate of mass loss from the entire Greenland ice sheet, and makes a significant contribution to sea level rise. For the WAIS as a whole the Shepherd et al. (2012) study found that over 1992 – 2011 the mass of the ice sheet changed by $-65 \pm 26 \text{ Gt year}^{-1}$.
43. The current changes in the Amundsen Sea Embayment region could represent a continuing response to historical forcing, a more direct result of increased delivery of warm Circumpolar Deep Water (CDW) (Jacobs et al., 2011) to the sub-ice-shelf cavities over recent decades, or, most likely, a combination of the two. Although changes in atmospheric circulation appear to be responsible for driving more CDW onto the continental shelf, there is no unambiguous link yet established with the more positive SAM index. The Amundsen Sea Low has been implicated as a causal factor in controlling the flux of CDW (Thoma et al., 2008), and changes in central tropical

Pacific sea surface temperatures may be more important in triggering the critical responses in the Amundsen Sea circulation (Steig et al., 2012).

44. Changes are less dramatic across most of the East Antarctic ice sheet, with the most significant changes close to the coast. The ice sheet shows interior thickening at modest rates and a mixture of moderate thickening and thinning among the fringing ice shelves (Pritchard et al., 2012). Melt trends from passive microwave data show less melt in coastal regions in recent years (2008, 2009). These anomalies are linked to trends in the summer SAM, which have suppressed warming over much of Antarctica during the satellite era. The Shepherd et al. (2012) study found that for 1992 – 2011 the mass of the East Antarctic ice sheet changed by $+14 \pm 43 \text{ Gt year}^{-1}$.
45. The Antarctic ice sheet provides a remarkable record of background levels of gases and pollutants. Pollutants in the Antarctic have been shown to be transported large distances. For example, black carbon measured in Antarctic ice cores comes from Southern Hemisphere biomass burning (Wang et al., 2010). Lake sediments also provide a temporal record of contamination from high temperature fossil-fuel combustion sources (Rose et al. 2012).

Sea level changes

46. Data from tide gauges and satellite altimeters suggest that in the 1990s-2000s global sea level rose at a rate of 3.3 mm per year (Woodworth et al., 2011), which is higher than predicted from earlier IPCC projections. The recent study of Shepherd et al. (2012), discussed above, reconciled the various satellite-derived estimates of changes in the mass of the Antarctic ice sheet and also estimated the contribution to sea level rise.

They found that over the period 1992 – 2011 the Antarctic Peninsula, West Antarctica and East Antarctic has respectively contributed $+0.05 \pm 0.04$, $+0.18 \pm 0.07$ and -0.04 ± 0.12 mm per year to global sea level rise. Combined this gives a contribution from the whole Antarctic ice sheet of $+0.20 \pm 0.15$ mm per year, which compares to $+0.39 \pm 0.14$ mm per year from the Greenland ice sheet.

The Southern Ocean

47. In surface waters, change is difficult to detect because an intensive seasonal cycle can induce large errors when there are only a few samples. However, around South Georgia observations exist since 1925 that are frequent enough to resolve the annual cycle, and these reveal a warming averaging 2.3°C over 81 years in the upper 150 m (Whitehouse et al., 2008). This is about twice as strong in winter as in summer, and is thought to be caused by a combination of the particular location of the island with respect to the footprint of the intensifying SAM over the Southern Ocean, and advection of warmed waters from upstream in the Southern Ocean circulation. There is also a strong warming of the upper ocean west of the Antarctic Peninsula, where temperatures have risen by nearly 1.5°C since the 1950s, accompanied by a marked summertime salinification caused by changes in the rate of sea ice production (Meredith and King, 2005). In coastal areas like Potter Cove (King George Island, South Shetlands), a c. 20 year data series showed sea surface temperatures increased during summers by 0.36°C per decade (Schloss et al., 2012). A significant portion of the ocean warming at the western Antarctic Peninsula is believed to be caused by near-surface ocean-atmosphere-ice interactions (Meredith and King, 2005); in

addition there has been a marked increase in the supply of warm CDW from the ACC onto the shelf in recent decades, providing heat and nutrients to increase retreat of the cryosphere and fuel biological production (e.g. Martinson et al., 2008)

48. The waters of the ACC have warmed more rapidly than the global ocean as a whole, increasing by 0.06°C per decade at depths between 300 – 1000 m over the 1960s to 2000s, and by 0.09°C per decade since the 1980s. The warming is more intense on the southern side of the ACC than north of it. A maximum increase of 0.17°C per decade was found in Upper Circumpolar Deep Water at depths of 150-500 m on the poleward side of the Polar Front (Gille, 2002; Böning et al., 2008). These changes are possibly consistent with a southward shift of the ACC in response to a southward shift of the westerly winds driven by enhanced greenhouse forcing and the loss of stratospheric ozone, however such a shift is hard to prove definitively, and previous assertions may have misinterpreted the satellite information on which they were based (Graham et al., 2012 and refs therein). Other causes for these changes have been proposed. North of the ACC a significant freshening of 0.01 salinity units per decade is observed since the 1980s (Böning et al., 2008). There is no evidence for an increase in ACC transport, despite the strengthening SAM (Meredith et al., 2011). Instead, recent studies suggest that an increase in wind forcing causes an increase in the intensity of Southern Ocean eddies rather than a sustained acceleration of the zonal transport. This then acts to increase the southward transport of heat in the Southern Ocean and hence may be a causal factor in the observed warming (Hogg et al., 2008; Meredith and Hogg, 2006).
49. Changes are evident in the character of the dense water (the Antarctic Bottom Water, AABW) formed around Antarctica and exported to lower latitudes. Globally there has been a contraction of AABW relative to a given temperature or density surface though

the degree to which this is indicative of warming versus a reduction in production rate is still being investigated (e.g. Purkey and Johnson, 2012). AABW warming has been strongest in the South Atlantic sector, but is significant circumpolarly (Purkey and Johnson, 2010). In addition, marked freshenings of AABW have been observed in the Ross Sea and Indian/Pacific sectors of the Southern Ocean (Jacobs et al., 2002; Rintoul, 2007). Recent indications are that the AABW exported from the Weddell Sea is also freshening decadal, due most likely to loss of the Larsen ice shelves and accelerated glacier flow, and consistent with the reported freshening of shelf waters on the eastern side of the Antarctic Peninsula (Hellmer et al. 2011).

Biogeochemistry

50. The Southern Ocean ventilates the global oceans and regulates the climate system by taking up and storing heat, freshwater, O₂ and atmospheric CO₂. Between 1991 and 2007 the concentration of CO₂ in the ocean increased south of 20°S in the southern Indian Ocean. At latitudes poleward of 40°S, CO₂ in the ocean increased faster than it did in the atmosphere, suggesting that the ocean became less effective as a sink for atmospheric CO₂. The stronger westerly winds lead to surface oceanic water being enriched with “natural” CO₂ from upwelling deep waters (Le Quéré et al., 2007) This saturates the carbon reservoir of the surface water limiting its ability to absorb carbon dioxide from the atmosphere. These changes are linked to the increase in wind strength driven by the more positive SAM. Ocean eddies will partially compensate for the increase in wind-driven overturning, however, a net increase in upwelling of a size important for the drawdown of anthropogenic carbon still results (Meredith et al.,

2012). An increase in the ocean's CO₂ content releases H⁺ ions and so makes the ocean more acidic. In addition to CO₂ changes, the Southern Ocean's oxygen content has also changed, showing some of the most significant decreases of any region of the global ocean (Helm et al., 2011). This is believed to be caused primarily by a reduction in water mass formation rates caused by increasing stratification as a result of surface ocean warming. Regional changes in biogeochemistry are also becoming apparent in the Southern Ocean. Particularly significant is the observation of changed phytoplankton communities in response to ocean climate change at the WAP (Montes-Hugo et al, 2009). These authors used three decades of satellite and field data to demonstrate a significant decline in summertime surface Chlorophyll-a, with the largest decreases equatorward of 63°S and with partially-compensating increases occurring farther south. The latitudinal variation in Chlorophyll-a trends reflects shifting patterns of ice cover, cloud formation, and windiness affecting water-column mixing.

Marine biology

51. The Southern Ocean ecosystem was significantly disturbed by whaling during the early part of the 20th Century, by sealing before that and by fishing since the mid-1900s. About 300,000 blue whales were killed, equivalent to more than 30 million tonnes of biomass. Stocks of humpback, fin, sei, and minke whales were similarly driven to near extinction (Simmons and Elliott, 2009). The krill stock was expected to increase due to this reduction in grazing pressure, but it did not, possibly because it has been reduced by the reduction in sea ice in the Bellingshausen Sea. While predation by

seals and birds increased, the total bird and seal biomass remains only a fraction of that of the former whale population. Humpback whales seem to be rapidly recovering (Ainley et al., 2010), whilst populations of other species remain low. Benthic communities and fish are expected to slowly recuperate from bottom fishing impacts, although evidence supporting this is not yet forthcoming. In case of further warming, commercially exploitable fishes, such as the southern blue whiting, could extend their distribution range into the Antarctic (Agnew et al., 2003). A spider crab (*Hyas araneus*) provides the only evidence of a transfer by ballast water to the Antarctic. For further examples of similar processes see Aronson et al. (2011). Current scientific understanding of fertilising phytoplankton "provides no basis to issue carbon credits" anymore (Vaughan and Lenton 2011).

52. The marine ecosystem of the Western Antarctic Peninsula (WAP) has been impacted over a 1000×200 km area (McClintock et al., 2008) by a significant reduction in the sea ice habitat by 85 days per year, and by secondary effects on the food web, or by a combination of both. These changes include:

- reduction of primary production in the ice;
- increases and decreases of primary production in the water column;
- a shift in phytoplankton from diatoms to smaller species (Schloss et al., 2012);
- increases of lantern-fish and salp biomass;
- an overall decrease of krill due to recruitment failures;
- local increases of krill and humpback whales (Nowacek et al., 2011);
- a decrease in Antarctic silver fish, a keystone species;
- shifts in the ranges of Adélie, Gentoo, and Chinstrap penguin populations to the south

(Stokstad, 2007), with a net reduction in the numbers of Adélie and Gentoos (Trivelpiece et al., 2011);

- shifts in the range of southern elephant seal populations to the south (Costa et al., 2010), and decreases in the north of their range (McIntyre et al., 2011);
- increased mortality in benthic organisms due to ice scouring (Barnes and Souster, 2011);
- identification of widespread populations of king crabs in the Palmer Deep (a deep basin within the Antarctic Peninsula continental shelf) and elsewhere, suggesting migration up-slope from the deep Southern Ocean benthos as the continental slope waters have warmed (Smith et al., 2012). Given that Antarctic shelf faunas are not adapted to degradation by crabs, changes in benthic community structure might result if these animals eventually colonise the continental shelf.

53. Beyond the WAP there have been other changes to the marine ecosystem:

- phytoplankton increased around the entire Antarctic, although the reasons for this are still unclear (Smith and Comiso, 2008);
- coastal waters are a stronger biogenic CO₂ sink than previously thought (Arrigo et al., 2008a) - the productive Ross Sea shelf area accounts for 27% of the CO₂ removed from the atmosphere by the entire Southern Ocean (Arrigo et al., 2008b);
- The Polar Front shifted to the south, which has resulted in a turn-over of the pelagic system and shrinking of the Antarctic pelagic habitat by an area of 2.4% (Sokolov and Rintoul, 2009);
- the microbial community shifted towards smaller cells increasing the significance of the microbial loop for CO₂ absorption in the sub-Antarctic (Evans et al., 2011);

- Emperor penguins in East Antarctica show low breeding success due to changes in the food-chain and sea-ice extent (Barbraud et al., 2011a) – nevertheless, recent satellite surveys show that there are many more breeding colonies of Emperor penguins than were previously known (Fretwell et al., 2012).

54. Disintegration of parts of the Larsen ice shelf on the eastern side of the Antarctic Peninsula (Gutt et al., 2011) caused several changes to the marine ecosystem:

- phytoplankton blooms became a new carbon sink (Peck et al., 2009a);
- there was an invasion of pelagic keystone species and their predators (Scheidat et al., 2011);
- benthic systems responded at different speeds (Hauquier et al., 2011);
- a few typical shelf-inhabiting pioneer species recruited successfully since the ice-shelf collapse and their populations grew significantly
- deep-sea species associated with the previous nutrient-poor ecosystem can temporarily benefit from enhanced phytoplankton blooms;
- areas with high rates of iceberg grounding were dominated by fast growing animals - icebergs can increase or decrease local primary production and change its composition (Schwarz and Schodlock, 2009).

55. As CO₂ dissolves in seawater the speciation of dissolved inorganic carbon is altered – a process termed ocean acidification. It potentially affects all marine organisms as it makes it more difficult for animals/plants to extract calcium carbonate (CaCO₃) from seawater to build skeletons and it influences other physiological processes. Availability of CaCO₃ is also lower at low temperatures, and Antarctic marine species have recently been demonstrated to have smaller skeletons than those from lower

latitudes (Watson et al. 2012). Pelagic keystone species suffer from the effects of acidification, but a range extension of the calcium carbonate coccolithophore *Emiliana huxleyi* is associated with neither warming nor acidification (Cubillos et al., 2007). Modern shells of the foraminiferan *Globigerina bulloides* weigh 30–35% less than those preserved in Holocene-aged sediments, which is consistent with predicted effects of ocean acidification (Moy et al., 2009). Few investigations have focused on abilities to compensate the negative effects or adapt to acidification, but a bivalve and a diatom are known to respond neutrally to acidification (Boelen et al. 2011, Cummings et al. 2011). Furthermore some echinoderms grow faster in lowered pH (DuPont et al. 2010), and such capacities for Antarctic species are yet to be reported.

Sea ice

56. For the first half of the 20th Century, ship observations suggest that the extent of sea ice around the Antarctic was greater than seen in recent decades, although the validity of such observations has been questioned. The sea ice extent data derived from satellite measurements from 1979 - 2010 show a positive trend of the annual mean Antarctic ice extent of 1.3% per decade (significant at <1% level). The trends in ice concentration have been linked to trends in ice motion, with wind-driven changes in ice advection being the dominant factor in driving the Antarctic sea ice extent increase (Holland and Kwok, 2012). The extent of Antarctic sea ice reached a new record maximum for the satellite era in 2012. The trend has been positive in all sectors except the Bellingshausen Sea, where sea ice extent has been significantly reduced. The greatest increase, at around 4.5% per decade, has been in the Ross Sea. The

Bellingshausen and Ross Seas have experienced increases and decreases respectively in the length of the sea ice season (Stammerjohn et al., 2008). The reduction of ice extent in the Bellingshausen Sea and its increase in the Ross Sea have been influenced by a deepening of the Amundsen Sea Low. In addition, Comiso et al. (2011) linked the variability in ice extent in the Ross Sea to changes in the SAM and secondarily to the Antarctic Circumpolar Wave. Warm winds brought south by the Amundsen Sea Low impede the advance of the sea ice to the west of the Peninsula, while cold, southerly flow west of the low over the Ross Ice Shelf enhances ice production over the Ross Sea. The reasons for the overall increase in Antarctic sea ice extent over the last 30 years are still under debate. Turner et al. (2009b) suggested that the loss of stratospheric ozone during the spring had played a significant role in the ice increase by increasing the strength of the Amundsen Sea Low and its associated surface winds. However, the modelling work of Sigmond and Fyfe (2010) suggested that the loss of ozone would result in a *decrease* of sea ice extent. Zhang (2007) and Liu and Curry (2010) suggested that ocean change and an intensification of the freshwater cycle, thus freshening the waters of the Ross Sea, had played a part in increasing the sea ice cover.

57. Analysis of an Antarctic Peninsula ice core suggested that sea ice decline in the Bellingshausen Sea is part of a trend that has occurred throughout the 20th Century. It may reflect a progressive deepening of the Amundsen Sea Low due to increasing greenhouse gas concentrations and, more recently, stratospheric ozone depletion. This longer-term perspective contrasts with the small increase in Antarctic sea ice that is observed in post-1979 satellite data (Abram et al., 2010).

Permafrost

58. There is little information on recent changes in permafrost temperature in the Antarctic.

On Signy Island the active layer (the permafrost layer experiencing seasonal freeze and thaw) increased in depth by 30 cm from 1963 - 1990, when the island was warming, then decreased by the same amount from 1990 - 2001, when it cooled slightly during the summer. In Northern Victoria Land between 1996 and 2009 the active layer exhibited a thickening trend (1 cm per year) comparable with the thickening rates observed in several Arctic locations. Over the same period (1999-2007) permafrost temperatures in Northern Victoria Land showed an increase of 0.1°C per year at depths greater than 0.3 m down to 3.6 m despite the stability of the air temperature. On the other hand in McMurdo Sound the temperature history, reconstructed by the permafrost thermal profile from boreholes 30 m deep and using an inversion procedure, suggested a slight cooling from 1998 to 2003 followed by a slight warming to 2008. During the IPY period several other boreholes were drilled mainly in Maritime Antarctica and in the coming years these data will provide a better estimate of permafrost and active layer responses to climate change.

Tropospheric chemistry

59. The elements cadmium (Cd), lead (Pb), bismuth (Bi), arsenic (As), and lithium (Li) are enriched across Antarctica relative to both ocean and upper crust elemental ratios. Global volcanic outgassing accounts for the majority of the Bi measured in East and West Antarctica and for a significant fraction of the Cd in East Antarctica. Nonetheless, global volcanic outgassing does not account for the enriched values of Pb or As. Local volcanic outgassing from Mount Erebus may account for a significant

fraction of the As and Cd in West Antarctica and for a significant fraction in East Antarctic glaze/dune areas. Despite potential contributions from local and global volcanic sources, significant concentrations of Pb, Cd, and As remain across much of Antarctica, suggestive of increased influence of anthropogenic emissions (Dixon et al., 2011b).

The Next 100 Years

60. Determining how the environment of the Antarctic will change over the next century has implications for policymakers and presents scientific challenges. The climate models used for assessing future climate change vary in complexity. Most of the current generation of climate models are climate “simulators”, in the sense that they attempt to represent, as realistically as is practical, known processes that are important in influencing climate change. They are the most realistic means we have currently of providing projections of future environmental behaviour, albeit crudely and at coarse resolution. The large regional climate variability around Antarctica makes it difficult to assess the skill of climate models in simulating recent change. However, there are clear biases in their representation of the mean state. Considering the implications of these biases for projections of 21st Century change is an important aspect of assessing data from collections of climate models, which give a range of responses to anthropogenic forcing.
61. Numerically-based biological models cannot yet approach the relative sophistication of models of the physics of the climate system, while physical models do not approach the level of spatial scale or resolution required for application to biological systems,

providing yet a further limitation on what can be said about biotic and ecosystem responses (Gutt et al, 2012).

62. The degree to which the Earth's climate will change over the next century is dependent on the success of efforts to reduce greenhouse gas emissions. The 2009 ACCE report focused on outputs from IPCC models that assumed a doubling of CO₂ and other gases by 2100 (the SRESA1B scenario). These outputs may be too conservative, given that some indicators are already changing faster than predicted in IPCC projections (Boden et al., 2012). There are also uncertainties on climate – carbon cycle feedbacks.

Atmospheric circulation

63. Coupled chemistry-climate models indicate that the recovery of the ozone hole will act to make the phase of the SAM more negative during the austral summer. However, general circulation models (GCMs) suggest that in other seasons increasing greenhouse gas concentrations are likely to act to continue strengthening the positive phase of the SAM resulting in stronger circumpolar westerly winds. There is still major uncertainty from models as to the relative size of changes in the SAM due to ozone-hole recovery and to increased greenhouse gases, which act in opposite senses on the SAM and with different seasonalities.

Temperature

64. The IPCC Fourth Assessment Report (AR4) models project significant surface warming over Antarctica to 2100 AD, by 0.34°C per decade over land and grounded ice sheets, within a range from 0.14 to 0.5°C per decade. Over land, the largest increase is projected for the high-altitude interior of East Antarctica. Despite this change, the surface temperature by the year 2100 will remain well below freezing over most of Antarctica and will not contribute to melting inland. Despite this, any increases in the number of ‘degree days above freezing’ in these continental inland locations, particularly at the ‘microhabitat’ scale relevant to the native terrestrial biota, will continue to exert a positive control on biological communities living there (Hodgson et al., 2010).
65. Based on AR4, the largest atmospheric warming projected by the models is over the sea ice zone in winter ($0.70 \pm 0.45^{\circ}\text{C}$ per decade off East Antarctica), because of the retreat of the sea-ice edge and the consequent exposure of the ocean.
66. While there is confidence in the overall projection of warming, there remains low confidence in the regional detail, because of the large differences in regional outcomes between models.
67. The annual mean warming rate in the troposphere at 5 km above sea level is projected to be 0.28°C per decade - slightly smaller than the forecast surface warming.
68. As yet neither the magnitude nor frequency of changes to extreme conditions over Antarctica can be forecast – something that biologists need to assess potential impacts. The extreme temperature range between the coldest and warmest temperature of a given year is projected to decrease around the coasts and to show little change over the interior.

69. A global warming of 3°C is expected to cause larger temperature change in Antarctica (due to polar amplification mechanisms). A 4°C warming in Antarctica within 100 years is abrupt compared to the past temperature variations documented in Antarctic ice cores (with the fastest change around 4°C per 1000 years during the last deglaciation). In Antarctica, local temperature changes corresponding to a global warming of 3°C reach temperature levels that were likely last encountered about 120 to 130,000 years BP, during the last interglacial period, albeit in response to a different perturbation (changes in insolation driven by changes in the Earth's orbit). The analogy between last interglacial and future changes is only partial due to different latitudinal and seasonal characteristics of orbital and greenhouse gas forcing, but many of the biological responses are expected to share similar trajectories.
70. The climate of the Antarctic is very variable on all timescales compared to lower latitude areas because of the non-linear interactions between the atmosphere, ocean and ice. This makes it difficult to separate natural climate variability from anthropogenic influences, such as an increase in greenhouse gas concentration. It also means that it is difficult to predict how the climate of the Antarctic and the Southern Ocean will change over the next few decades when the greenhouse gas concentration increases are relatively small compared to pre-industrial levels.

Precipitation

71. The current generation of numerical models underestimates precipitation across the Antarctic continent. This is due to problems in parameterizing key processes that drive precipitation (e.g. because polar cloud microphysics is poorly understood), and

because the smooth coastal escarpment in a coarse resolution model causes cyclones to precipitate less than they do in reality. Warmer air temperatures and associated higher atmospheric moisture in most models cause net precipitation to increase in the future. Most climate models simulate a precipitation increase over Antarctica in the coming century that is larger in winter than in summer. Model outputs suggest that the snowfall over the continent may increase by 20% compared to current values. With the expected southward movement of the mid-latitude storm track we can expect greater precipitation and accumulation in the Antarctic coastal region. The form that precipitation takes is of biological significance (liquid water is immediately available to biota whereas snow is not).

The ozone hole

72. By the middle of the 21st Century springtime concentrations of stratospheric ozone are expected to have significantly recovered and will have almost fully recovered by the end of the 21st Century. Models disagree about the timing of the recovery, but assuming future atmospheric dynamics are similar to today's, it has been forecast on empirical grounds that ozone loss rates will begin to decline noticeably between 2017 and 2021 (Hassler et al., 2011). Increased greenhouse gas concentrations will have further cooled the stratosphere, which increases ozone in its global balance of chemical reactions, so ozone amounts outside the ozone hole period should then be greater than in the 1970s.
73. Greenhouse cooling in the upper mesosphere is offset by both radiative and dynamical feedbacks associated with CO₂ (radiative transfer, solar heating in the 2 and 2.7 μ m IR

bands and modification of mesospheric circulation) and the ozone depletion in recent decades. In the case of the latter, larger mesosphere/lower thermosphere region temperature changes may be expected over the next few decades as ozone levels recover.

Tropospheric chemistry

74. Various trace gases, such as dimethyl sulphide (DMS) generated by plankton, are released from the oceans and sea-ice (Asher et al., 2011) around Antarctica. In a warmer world, with reduced sea ice extent, emissions of gases such as DMS would likely increase, with a wintertime minimum and an extended summer maximum. DMS is a source of cloud condensation nuclei (CCN) via its oxidation to sulphate. Increasing the number of CCN may increase cloudiness and albedo influencing the Earth's climate.

Terrestrial biology

75. Increased temperatures may promote growth and reproduction, but also locally cause drought and associated effects. Changes to water availability have a greater effect than temperature on microbial, vegetation and faunal dynamics. Future regional patterns of water availability are unclear, but climate models predict an increase in precipitation in coastal regions. An increase in the frequency and intensity of freeze–thaw events

could readily exceed the tolerance limits of many endemic invertebrates. With increases in temperature, many terrestrial species may exhibit faster metabolic rates, shorter life cycles and local expansion of populations. Even subtle changes in temperature, precipitation and wind speed will probably alter the catchment of lakes, and of the time, depth and extent of their surface ice cover, water volume and chemistry, with resulting effects on lake and dependent terrestrial ecosystems. Warming also increases the likelihood of invasion by more competitive alien species carried by water and air currents, humans and other animals. Changes may alter the relative importance of different mechanisms and opportunity for dispersal and establishment of both native and exotic biota. Notably, current evidence suggests that humans may be responsible for two or more orders of magnitude of establishment events of non-indigenous species to Antarctica than would occur with natural colonisation processes (see discussion in Hughes and Convey, 2012).

The terrestrial cryosphere

76. Existing ice-sheet models do not properly reproduce the observed behaviour of ice sheets, casting doubt on their predictive value. The models fail to take into account mechanical degradation (e.g. water causing cracks to propagate in summer), changing lubrication of the base of the ice by an evolving subglacial hydrological regime, or the influence of variable sub-ice-shelf melting on the flow of outlet glaciers and ice streams. Predictions of the future state of ice sheets are based on a combination of inferences from past behaviour, extension of current behaviour, and interpretation of proxy data and analogues from the geological record.

77. The most likely regions of future change are those that are changing most today. Warm CDW will continue to flow onto the continental shelf in the Amundsen Sea, melting the underside of the ice sheets and glaciers. If sea surface temperatures in the central tropical Pacific play a role in controlling the atmospheric forcing on the inflows, the future warming in that region predicted by coupled climate models would have the effect of strengthening the inflows. It has been suggested (Vaughan and Spouge, 2002) that there is a 30% probability that loss of ice from the West Antarctic ice sheet could cause sea level to rise at a rate of 0.2 cm per year, and a 5% probability it could cause rates of 1 cm per year. In addition, the ice shelves in the Amundsen Sea Embayment could be entering a phase of collapse that could lead to de-glaciation of parts of the West Antarctic Ice Sheet. Ultimately, this sector could contribute 1.5 m to global sea level, so a contribution from this sector alone of some tens of centimetres by 2100 cannot be discounted. These estimates are based upon the assumption that the ice sheets will respond linearly to warming and that sea level contributions will be confined to the West Antarctic ice sheet. Evidence for past abrupt changes in climate and inclusion of all marine-based regions could significantly raise these estimates.
78. On the Antarctic Peninsula, most of the effects leading to loss of ice are confined to the northern part, which contains ice equating to a few centimetres of global sea-level rise. Increased warming will lead to southerly progression of ice shelf disintegrations along both coasts. These may be preceded by increases in surface and basal melting, and/or progressive retreat of the calving front. Prediction of the timing of ice shelf disintegration is not yet possible, but seems to relate to the progression of the -9°C isotherm. Removal of ice shelves will cause glaciers to speed up as buttressing forces are reduced. The total volume of ice on the Peninsula is $59,158 \text{ km}^3$, equivalent to $147 \pm 64 \text{ mm}$ of sea-level or roughly one quarter of the sea-level contained within all

glaciers and ice caps outside of the Greenland and Antarctic ice sheets. Increased warming is expected to lead to a substantial contribution to sea-level rise from the Peninsula. Radić and Hock (2011) have estimated the contribution to sea level rise by mass losses from the peripheral glaciers and ice caps from Antarctica at 21 ± 12 mm sea level equivalent (mostly from the Antarctic Peninsula region) over the period 2001-2100.

Sea level

79. The IPCC's Fourth Assessment Report projected a range of global sea-level increase from 18 to 59 cm between 1980-1999 and 2090-2099. This did not include a contribution from the dynamically driven changes in flow for portions of either the Greenland or Antarctic ice sheets. Ice loss from Antarctica is expected to have major implications, particularly for Northern Hemisphere sea level. Regression modeling (Rahmstorf, 2007; Vermeer and Rahmstorf, 2009) suggests that by 2100 global sea level may rise by up to 1.94 m rather than the IPCC's suggested 59 cm. Sea level will not rise uniformly, not least because of glacial isostatic adjustment, which makes areas freed of ice rise, and surrounding areas sink. The spatial pattern of sea-level rise projections shows a minimum in sea-level rise in the Southern Ocean and a maximum in the Arctic Ocean.

Biogeochemistry

80. Model projections for the remainder of the 21st Century suggest that the Southern Ocean will be an increased sink of atmospheric CO₂. The magnitude of the uptake will depend on how the ocean responds to increases in ocean warming and to stratification, which can drive both increases in CO₂ uptake through biological and export changes, and decreases through solubility and density changes. Changes in atmospheric circulation (e.g. increases in the intensity of the southern hemisphere westerly winds associated with the SAM being in a positive phase) may affect the rate of deep ocean upwelling, bringing old CO₂ to the surface and reducing the efficiency of the Southern Ocean CO₂ sink.

Marine biology

81. Growth of phytoplankton is shaped by climate (Montes-Hugo and Yuan, 2012) and determines the capacity of the Southern Ocean to act as a biological CO₂ sink or source. Phytoplankton are exposed to changes in (a) sea ice, (b) nutrients, by upwelling or remineralization, (c) micronutrients, e.g. by wind driven iron fertilisation, (d) stratification of the water column, (e) water characteristics: light, salinity, temperature, CO₂, acidity, (f) habitat size and (g) biological interactions. Changes in primary production have already impacted and will continue to impact other marine organisms through provision of their primary food source. Metabolites derived from algae can accelerate climate change.

82. A theoretical Southern Ocean with only 5% of today's ice extent would produce 29% more algae due to the loss of sea ice as their habitat and an extension of pelagic zones (Arrigo and Thomas, 2004). Ice is not the exclusive habitat for most small organisms,

thus, their overall species richness will not be affected significantly. Penguin colonies north of 70°S are projected to decrease, but growth might occur to a limited extent south of 73°S (Ainley et al., 2010). Negative effects would be evident in sea ice obligatory pack ice seals: crabeater, leopard, Ross (Siniff et al., 2008), and ice-avoiding penguin species are likely to continue their southward expansion of range. Climate-induced potential effects of climate change on biogeographic ranges of selected mammals, including whales, were assessed by Learmonth et al. (2006). Some Icefish and pelagic fish species will also suffer from sea-ice reduction since they depend on the ice shaping their habitat.

83. Model projections suggest warming of 0.5 to 0.75°C by 2100 AD of most surface and bottom waters, with exceptions in part of the more stable Weddell Sea (Hellmer et al., 2012) and above average changes near the ACC (Sololov and Rintoul, 2009). Thus, the effects on the marine biota may be less than has been feared from laboratory experiments. Benthic organisms including fish are especially sensitive to warming. Most species have upper lethal temperatures below 10° C. Some can survive only less than a 5°C change in combination with oxygen limitations (Peck et al., 2009b). Performance of critical activities can be reduced long before lethal levels are reached. Species predicted on the basis of short-term experiments to suffer under only minor warming are found to be less impacted under longer term acclimatisation (Morley et al., 2011), e.g. at 8°C above their usual temperature, such as the fish *Pagothenia borchgrevinki* (Franklin and Seebacher, 2009). However, links between short-term temperature tolerance and prospects for surviving changing environments seem to exist (Barnes et al., 2010). Several marine invertebrates are distributed across sites or depths with a greater temperature range than their 'typical Antarctic conditions', e.g. around South Georgia (Morley et al., 2010). Nevertheless, it must be assumed that

some of the already observed climate-induced impacts to the ecosystems will continue. Increasing intrusion of warmer water onto the shelf will result in a continued decline in habitat for crabeater seals, but elephant seals and possibly fur seals are likely to benefit regionally (Costa et al., 2010). Genomic studies e.g. on the physiologically important nitrogen monoxide production and neuroglobin genes of icefish (Cheng et al., 2009) may help to predict how icefish can cope with global change. Black-browed albatross and snow petrel populations are predicted to respond negatively to sea surface temperature warming and decline of sea ice (Barbraud et al., 2011b). As mentioned earlier, a hypothesised spread of king crabs up onto the shelf within 1-2 decades (Smith et al., 2012) could cause a complete ecological regime shift.

84. There are measurable changes in marine carbonate chemistry (ocean acidification) that have been shown to change physiological and biogeochemical systems. In the second half of this century the aragonite saturation horizon is likely to reach the ocean surface in parts of the Southern Ocean, making the entire water column undersaturated. The planktonic food chain, benthic life, remineralisation processes including the "microbial loop" and the carbonate flux to the deep-sea (Hunt et al., 2008) will all be significantly affected. Many groups including Foraminifera, corals, molluscs (McClintock et al., 2009), echinoderms (McClintock et al., 2011), and coralline algae are potentially threatened unless they have mechanisms to prevent shell dissolution (see e.g. Fabry et al., 2009). The observed transition from larger diatoms to smaller cryptophytes would result in a 40-65% decrease of carbon supply to higher trophic levels, but to increased food supply to the benthos, from which suspension feeders might not benefit as much as the more opportunistic deposit feeders (for such benthic dynamics see Sumida et al. 2008). The Southern Ocean is at higher risk than other

oceans because it has low saturation levels of CaCO_3 (Comeau et al., 2012). Acidification is a serious threat because organisms cannot "escape" if the entire ocean is affected.

85. Increasing CO_2 can also lead to increased phytoplankton productivity, altered species composition and effects on biological carbon cycling creating climate feedbacks (Moreau et al., 2012).

86. Direct and other disturbances that might occur include (Brandt and Gutt, 2011; Somero, 2012 and references therein):

- increased ice scouring, leading to reduced benthic diversity in shallow depths;
- increased scouring of large icebergs at greater depths leading to an increase of regional benthic biodiversity;
- long-term decreases in ice scour by icebergs, resulting in decreased biodiversity;
- lack of anchor ice, preventing "explosive" growth of opportunistic benthic species;
- increased coastal sedimentation associated with deglaciation on land, smothering benthos and hindering feeding (Brey et al., 2011);
- freshening of surface waters changing buoyancy especially of eggs, and supporting the greater stratification of the water column with further impact on the food web and the response of the benthic system;
- continuation of ice shelf disintegration, initiating major ecosystem regime shifts;
- slight deoxygenation of surface waters, leading to more serious deoxygenation in deeper layers.

87. It seems unlikely that species will become extinct by 2100 due to warming, either because they are able to cope ecologically and physiologically with the predicted

environmental changes, or because they are not restricted in their occurrence to an area with a harmful temperature increase (Brandt and Gutt, 2011).

Ocean circulation and water masses

88. Ocean models have improved in recent years in resolution and in their representation of unresolved processes. Grid spacing as small as 10 km in the horizontal is not uncommon, yet even this relatively high resolution is not sufficient to resolve the smaller eddy structures at high latitudes. Small topographic features are crucial to resolve as well, e.g. for shelf-ocean exchange, and models are not able to capture this phenomenon very well. Given the key role of ocean eddies in north-south heat and property transport in the Southern Ocean, these limitations are important to overcome. Ocean models generally predict a very small net intensification of the ACC in response to the overall southward shift and intensification of the westerly winds over the Southern Ocean. However, there may be large regional differences in any meridional shift in the location of the ACC, with a northward change in the current cores possible in some locations. The increase in ACC transport projected for 2100 reaches a few Sverdrups (1 Sv = one million cubic metres/second) in the Drake Passage, i.e. less than conventional techniques are able to measure. The enhanced winds induce a small southward displacement of the core of the ACC (less than 1° in latitude on average). Model-based predictions of future ACC flow and structure are, however, currently inadequate.
89. The observed mid-depth and surface layer warming of the Southern Ocean is projected to continue (Sen Gupta et al., 2009). Ocean ventilation could be enhanced because of

enhanced divergence of surface waters induced by the increase in the wind stress and associated upwelling, however stronger stratification caused by heating and ice melt will counteract this and may suppress overturning circulation and ventilation, as per Helm et al. (2011). The apparent contraction of the abyssal layer of AABW in the Southern Ocean has been attributed to the weakening of up to -6.9 Sv in all the regional sources combined during the past few decades (Purkey and Johnson, 2012), i.e. a dramatic slowdown of the lower limb of the global thermohaline circulation based solely on previous estimates of AABW production (8.1 Sv). Whether or not this contraction reflects changes in source strength or different modes of formations is not yet clear, hindering predictive skill concerning future patterns of abyssal warming. Model calculations suggest that bottom water formation will be reduced and deep water will slightly warm by 2100 (Sen Gupta et al., 2009), though IPCC-class models do not represent Antarctic Bottom Water formation in anything approaching an acceptable way.

Sea ice

90. The AR4 climate models suggest that the annual average total sea-ice area will decrease by $2.6 \times 10^6 \text{ km}^2$, or 33% (Bracegirdle et al., 2008). Most of the retreat is expected to be in winter and spring, so decreasing the amplitude of the seasonal cycle of sea ice area. The current generation of climate models is not able to provide a precise regional picture of the changes to be expected.

Permafrost

91. It is likely that there will be a degradation of permafrost conditions, accompanied by subsidence of ground surface, development of thermokarst, and triggering of mass movements. Active layer thickening is also predicted, although the link with air temperature is not so clear and other factors like snow cover and solar radiation significantly influence its evolution. Active layer thickening could have a significant impact on vegetation and soil ecosystems. Change is most likely in the northern Antarctic Peninsula and the South Shetland and South Orkney Islands and coastal areas in East Antarctica. The forecast changes imply risks to infrastructure and to ecosystems.

Concluding remarks

92. The climate of the high latitude areas is more variable than that of tropical or mid-latitude regions and has experienced a wide range of conditions over the last few million years. The snapshot we have of the climate during the instrumental period is limited in the long history of the continent, and separation of natural climate variability from anthropogenic influences is difficult. However, the effects of increased greenhouse gases and decreases in stratospheric ozone are already evident. The effects of the expected increase in greenhouse gases over the next century, if they continue to rise at the current rate, will be remarkable because of their speed, and because of polar amplification of the global warming signal. It should be borne in mind that equally rapid change was also typical in past deglaciations, e.g. 20,000 years ago at the end of the LGM. Removal of the surface cooling effect of the ozone hole as it diminishes in

extent will accelerate the increase in surface temperature. We can make reasonably broad estimates of how quantities such as temperature, precipitation and sea ice extent might change, and consider the possible impact on marine and terrestrial biota. We cannot yet say with confidence how the large ice sheets of Antarctica will respond, but observed recent rapid changes give cause for concern – especially for the stability of parts of West Antarctica.
