Long-Run Growth Uncertainty

Pei Kuang\textsuperscript{a},* Kaushik Mitra\textsuperscript{a,†}

\textsuperscript{a} University of Birmingham

Abstract

Observed macroeconomic forecasts display a positive correlation between expectations of long-run growth of endogenous variables (e.g., output) and cyclical activity. Existing business cycle models appear inconsistent with the evidence. This paper presents a model of the business cycle in which households have imperfect knowledge of long-run growth rate of endogenous variables and continually learn about these growth rates. The model features comovement and mutual influence between households' growth expectations and market outcomes. It can replicate the evidence on growth forecasts and suggests that optimism and pessimism about long-run growth rates is a crucial ingredient in understanding business cycle fluctuations.

Keywords: Trend, Expectations, Business Cycle

†This draft: 21 March 2016. We are very grateful for comments by an anonymous referee, the associate editor and the editor which significantly improved the paper. Thanks to Klaus Adam, Christian Bayer, Jess Benhabib, George Evans, Wouter den Haan, Jonas Dovern, Cars Hommes, Juan Jimeno, Albert Marcet, Ramon Marimon, Bruce McGough, Bruce Preston, Ricardo Reis, Raf Wouters, Tony Yates, participants at the 2014 Mannheim workshop in Quantitative Macro, 2014 Barcelona GSE Summer Forum, 2014 Conference on Behavioral Aspects in Macro and Finance (Milan), 2014 Kent macroeconomics workshop, 2015 Money, Macro and Finance Conference (Cardiff) and seminar participants at Reserve Bank of New Zealand for helpful comments.
1 Introduction

Economic agents and policymakers in reality face uncertainty about the (unobserved) long-run growth rate of endogenous economic variables (e.g., income, aggregate output, asset prices) analyzed in general equilibrium business cycle models. Agents’ perceived long-run growth determines consumption and financial investment decisions as well as the formulation of monetary and fiscal policy by policymakers. Observed macroeconomic forecasts—documented in Section 2.1—display gradual learning by economic agents that gives rise to very persistent gaps between forecasts of long-run growth of endogenous variables and the corresponding trend growth estimate constructed e.g., from the Hodrick-Prescott (HP) filter. More importantly, Section 2.2 demonstrates, for the first time to our knowledge, a positive correlation between expectations of long-run output growth (or output per hour growth) and detrended aggregate output, consumption, investment and hours.

Perhaps surprisingly, existing business cycle models – including full and imperfect information Rational Expectations (RE) models and adaptive learning (AL) models – do not consider this long-run growth uncertainty. These models, as explained later, appear inconsistent with the evidence mentioned above. The paper develops a real business cycle (RBC) model where agents have imperfect knowledge of the long-run growth rate of endogenous variables and continually learn about these growth rates. The model can replicate this evidence and suggests an important role for shifting long-run growth expectations in business cycle fluctuations.

Clearly, agents in full-information RE models have exact knowledge of the long-run growth rate. A separate class of models entertain weaker informational assumptions where agents are uncertain and learn about the exogenous (productivity) process, e.g. Edge et al. (2007) and Boz et al. (2011). However, this type of learning models do not produce persistent gaps between forecasts of long-run growth rate of endogenous variables and the actual long-run growth rates of these variables, as a consequence of RE. This suggests a separate role for learning of endogenous variables. Moreover, these models produce constant long-run
growth forecasts which do not correlate with cyclical activity.\footnote{An exception is the case when trend productivity growth contains a unit root, this correlation is then counterfactually negative; see Section 6.2.}

A large class of models replace RE by AL and analyze the resulting empirical performance, such as Milani (2007) and Eusepi and Preston (2011). These AL models, however, assume that agents learn about detrended endogenous variables. We show that this widely adopted methodology in the AL literature effectively assumes that agents have \textit{exact} knowledge about the long-run growth of endogenous variables (as under RE). Again, in this type of models, the long-run growth forecasts are constant and the correlation between long-run growth forecasts and cyclical activity is \textit{zero} by construction, which is inconsistent with the evidence on long-run forecasts.

Our model differs from existing models by relaxing households’ knowledge of the long-run growth of endogenous variables. Agents do not have sufficient information to derive the equilibrium mapping from primitives (e.g. preferences, technology) to the long-run growth rate of endogenous variables; instead they approximate the equilibrium mapping by extrapolating historical patterns in observed data. Their subjective beliefs may not be the same as the true equilibrium distribution. They forecast variables that are exogenous to their decision problems and make optimal economic decisions under their subjective beliefs, in line with Preston (2005, 2006), Eusepi and Preston (2011) and Adam and Marcet (2011).

During economic expansions (recessions), households tend to extrapolate from past observations and hence are optimistic (pessimistic) about long-run growth rates of the economy. Households make optimal economic decisions based on this optimism (pessimism). The resulting equilibrium outcomes reinforce agents’ optimism (pessimism) about long-run growth rates. The self-referential property—comovement and mutual influence between the long-run growth expectations and market outcomes—is crucial to produce the positive correlation between long-run growth forecasts and cyclical activity present in the data.

The results of this paper are similar in spirit to Adam et al. (2015) which documents a positive correlation between stock price growth expectations (at different horizons) and price
dividend ratio (which may be interpreted as detrended stock prices) in U.S. stock markets. They show RE asset pricing models tend to produce a negative correlation between expected returns and price dividend ratio. Taking their paper and ours together, learning about the (trend) growth of endogenous variables is the key to producing these positive correlations and in explaining phenomena that are puzzling from the viewpoint of RE. The interplay of growth expectations and market outcomes is crucial in explaining the boom-bust cycle in U.S. stock markets (see Adam et al., 2015), equity pricing facts in the U.S. (see Adam et al., 2016) and house prices in major industrialized economies (see Adam et al., 2012).

Our learning model suggests a crucial role for optimism and pessimism about long-run growth rates in understanding business cycle fluctuations. Business cycle models with RE usually rely on large exogenous shocks to reproduce salient features of cyclical fluctuations. This is viewed as unrealistic by many economists e.g. Cochrane (1994) and Kocherlakota (2009). Learning strongly amplifies the response of aggregate activities to economic shocks. To match the HP-filtered output volatility in the data, our learning model requires 47% smaller standard deviation of productivity shocks relative to the RE version of the model. The relative volatility of growth rate of productivity shocks to output is 0.143 in the learning model, which is close to the value 0.131 estimated in Burnside et al. (1996). The learning model also (1) generates 119% and 50% higher standard deviation in hours and investment relative to the RE version of the model and is closer to the data, (2) produces positive comovement between consumption, investment, working hours and output, and (3) improves the internal propagation by producing the degree of positive autocorrelation observed in output growth as well as the growth of consumption, investment and hours present in the data.

The rest of the paper is organized as follows. Section 2 presents evidence on observed forecasts and Section 3 the model setup. Our learning model is described in Section 4 and the quantitative results are presented in Section 5. Section 6 shows that full and imperfect information RE models are inconsistent with this evidence. Section 7 shows that existing
AL models appear inconsistent with the evidence. Section 8 concludes.

2 Observed Macroeconomic Forecasts and Cyclical Fluctuations

This section documents evidence on observed long-run growth forecasts and their positive comovement with cyclical macroeconomic variables that we seek to quantitatively replicate with our learning model.

2.1 Long-Run Growth Forecasts

This section presents forecasts of the long-run growth rate of real gross domestic product (GDP) and real output per hour. In the left panel of Figure 1, the solid line is the U.S. annual real GDP growth from 1991 to 2014. The dashed line is the HP-filtered trend output growth with a smoothing parameter of 100. Three proxies for real-time forecasts of long-run output growth are also plotted. One proxy is the real-time potential output growth estimates prepared by the U.S. Council of Economic Advisors (CEA), reported in its annual Economic Report of the President (ERP) and published in January (or February) of each year. The second proxy is the forecast of the average rate of potential real GDP growth over the next 10 years reported by the Congressional Budget Office, (CBO) in its annual Budget and Economic Outlook. The third proxy is the median forecast in the Survey of Professional Forecasters (SPF) for the annual average rate of real GDP growth over the next 10 years published in February of each year. The right panel plots the same (five) times series for real output per hour growth.

---

2 Edge et al. (2007) interpret the HP-filtered estimate as a long-run trend growth estimate.

3 Potential output growth is viewed as output growth in the long-run. Therefore, the CEA also regards the estimates as the long-run growth forecasts in the annual ERP.

4 In the right panel of Figure 1, the real output per hour is nonfarm business sector real output per hour from the FRED database. We use the longest available dataset for CBO and SPF forecasts. For CBO forecasts, the earliest available data is 1991 for output growth forecasts and 1995 for output per hour growth forecasts, while for SPF, the earliest available data is 1992 for both long-run output and output per hour growth.
The observed forecasts suggest gradual learning of the long-run growth rate of output (and output per hour) that gives rise to very persistent gaps between expectations of long-run output growth (output per hour growth) and HP-filtered trend output growth (output per hour growth). During the late 1990s and early 2000s, there was an acceleration of long-run real output growth and long-run output per hour growth, while agents only gradually revised their growth expectations upward and persistently underpredicted the long-run growth rates. Thereafter, there was a period of slower long-run growth; agents only gradually revised the long-run growth expectations downward and persistently over-predicted the long-run growth forecasts. We use CEA forecasts from 1991 since the forecasts before 1991 are missing or ambiguous to interpret for many years.
The autocorrelation for gaps between forecasts of long-run real output growth and the HP-filtered trend output growth is 0.96 for all three sources of forecasts, while the autocorrelation for the corresponding gaps using output per hour growth is 0.93, 0.96, 0.94 for CEA, CBO, and SPF forecasts, respectively.\footnote{Short-term forecasts for a wide range of macroeconomic variables also display persistent errors, as documented in e.g., Eusepi and Preston (2011). Edge and Rudd (2012) find that the Federal Reserve’s Greenbook output gap revisions are highly persistent and have an autocorrelation coefficient on the order of 0.9 during 1996-2006. They suggest this points to gradual learning of the economy’s trend growth by the Federal Reserve.}

2.2 Comovement Between Long-Run Growth Forecasts and Cyclical Activity

This section documents—to our knowledge for the first time—the comovement between long-run growth expectations and cyclical aggregate activity. Panel A (B) of Table 1 reports the correlation between expectations of long-run real GDP growth and detrended real output, investment, consumption and working hours using CEA forecasts (CBO forecasts).\footnote{Data is from the Bureau of Labor Statistics. Output is real GDP. Nominal consumption is constructed as the sum of nondurable goods, services, and government expenditures. Nominal investment is calculated as the sum of private residential investment, equipment and software, and consumption durable goods. Nominal consumption and investment are deflated by using the GDP deflator. For hours, we use the data of total hours in Hall (2014) from 1989-2013 available at http://web.stanford.edu/~rehall/Recent_Unpublished_Papers.html.} Three detrending methods are considered: linear, quadratic detrending and HP filter with smoothing parameter 100.

There is a strong positive correlation between long-run output growth forecasts and detrended real output, investment, consumption and working hours, which is robust to three sources of forecasts and different detrending methods. The long-run growth forecasts tend to be high during expansions, and contrariwise during contractions. Taking CEA forecasts as an example, the corresponding correlation coefficient for output is $0.52 - 0.76$, consumption $0.44 - 0.82$, investment $0.49 - 0.75$, and hours $0.43 - 0.58$, depending on the detrending methods.
methods. The use of CBO forecasts yields similar correlations. The numbers reported in parenthesis in Table 1 are autocorrelation robust p-values for the hypothesis that the correlation is smaller or equal to zero.\(^7\) All correlations are statistically significant at 5% level except for the one corresponding to the combination of detrended consumption and linear trend;\(^8\) most robust p-values in Table 1 are no more than 1%. Similar positive correlations and robust p-values are obtained using SPF forecasts; see Online Appendix A. This Appendix also reports a strong positive correlation between expectations of long-run output per hour growth forecasts and detrended output, consumption, investment and hours, which is robust to three sources of forecasts and different detrending methods.

3 Model Setup

Our model is a standard RBC model with four main features: King-Plosser-Rebelo (KPR) non-separable preferences between consumption and leisure, constant returns to scale technology, variable capital utilization, and a random walk with drift productivity process. Households have KPR non-separable preferences between consumption and leisure which is consistent with a balanced growth path; see e.g. King and Rebelo (1999).\(^9\) The representative household maximizes

\[
\hat{E}_t \sum_{t=0}^{\infty} \beta^t u(C_t, L_t); \quad u(C_t, L_t) = \frac{C_t^{1-\sigma} v(1 - L_t)}{1 - \sigma}
\]

---

\(^7\)The test allows for contemporaneous correlation, as well as for cross-correlations at leads and lags. The p-values are computed using the result in Roy (1989) and are based on the sampling width of one year (but are not sensitive to this choice).

\(^8\)Using CEA (CBO) forecasts, the robust p-value for the correlation between long-run output growth forecasts and linearly detrended consumption is 0.05 (0.10). We note, however, the corresponding p-value for testing contemporaneous correlation only is lower, namely, 0.03 (0.08).

\(^9\)Households are assumed to have the same preferences and constraints, firms the same technology, and beliefs are homogenous across agents (though no agent is assumed to be aware of this); hence, in what follows we do not distinguish explicitly between individual agents and firms.
subject to the flow budget constraint

\[ C_t + K_{t+1} = R^K_t(U_tK_t) + W_tH_t + (1 - \delta(U_t))K_t. \]

\( \hat{E}_t \) denotes the subjective expectations of agents for the future, which agents hold in the absence of RE. RE analysis is standard. \( C_t, L_t, H_t, K_t, U_t \) are consumption, leisure, hours, capital and capacity utilization rate. \( W_t \) and \( R^K_t \) are the wage rate and rental rate for capital services. \( \beta \) is the discount rate between 0 and 1. \( \sigma > 1 \) and \( \nu', \nu'' > 0 \). Capacity utilization in the data displays pronounced procyclical variability (see King and Rebelo (1999)) and is used to improve the fit of the model. Capital depreciation is assumed to increase with capacity utilization \( U_t \) according to the function \( \delta(U_t) = \theta - 1 U_t^\theta \) where \( \theta > 0 \).

There are a continuum of identical competitive firms of mass one. Each produces the economy’s only good \( Y_t \) using capital \( K_t \) and labor \( H_t \) as inputs according to the production function

\[ Y_t = (U_tK_t)^\alpha (X_tH_t)^{1-\alpha} \tag{1} \]

where \( 0 < \alpha < 1 \). Each firm maximizes profits, \( \Pi_t = Y_t - R^K_tU_tK_t - W_tH_t \), choosing labor and capital inputs and taking factor prices as given. Stochastic variations in the technology factor are the source of aggregate fluctuations and we assume that the technology factor \( X_t \) is a random walk with drift following Rotemberg and Woodford (1996) and Eusepi and Preston (2011), i.e.

\[ \log(X_t/X_{t-1}) = \gamma_t = \log(\gamma) + \hat{\gamma}_t \tag{2} \]

where \( \hat{\gamma}_t \) is an independently and identically distributed (i.i.d) random variable with zero mean and standard deviation \( \sigma_\gamma \) and \( \gamma > 0 \). Details of the first order conditions of the household and firm, steady state and the log-linear approximation are presented in Online Appendix B.

We denote detrended variables by lower case letters. Balanced growth requires consumption, investment, output, the capital stock, and real wages to grow at the rate of the
stochastic trend so that \( k_t = \frac{K_t}{X_{t-1}}, y_t = \frac{Y_t}{X_t}, c_t = \frac{C_t}{X_t} \) etc are stationary. Hours and the rental rate of capital are stationary. Log-linearizing the model, utilizing the labor supply condition and iterating the flow budget constraint yield the intertemporal budget constraint

\[
\varepsilon_c \tilde{E}_t \sum_{T=t}^{\infty} \beta^{T-t} \tilde{c}_T = \tilde{\beta}^{-1} k_t + \tilde{E}_t \sum_{T=t}^{\infty} \beta^{T-t} \left[ \varepsilon_w \tilde{w}_t + \tilde{R} \tilde{R}_t K - \tilde{\beta}^{-1} \tilde{\gamma} T \right]
\]

\( \tilde{\beta} \) is growth-adjusted discount factor. Hatted variables are percentage deviations from the steady state. The coefficients \( \varepsilon_w \) and \( \varepsilon_c \) are constant composite parameters. This equation says that the expected present value of consumption must be equal to the initial capital stock plus the expected present value of wage and rental income.

Utilizing the consumption Euler equation and the intertemporal budget constraint, we obtain the consumption decision rule

\[
\hat{c}_t + \sigma^{-1} \psi (1 - \sigma) \hat{H}_t = \frac{(1 - \chi)(1 - \tilde{\beta})}{\varepsilon_c} \left[ \tilde{\beta}^{-1} k_t + \tilde{R} \tilde{R}_t K - \tilde{\beta}^{-1} \tilde{\gamma} t + \left( \varepsilon_w + \varepsilon_c \frac{\chi}{1 - \chi} \right) \tilde{w}_t \right] \\
+ \tilde{E}_t \sum_{T=t}^{\infty} \beta^{T-t} \Delta_1 \tilde{R}_{T+1} + \tilde{E}_t \sum_{T=t}^{\infty} \beta^{T-t} \Delta_2 \tilde{w}_{T+1}
\]

Equation (3) says that the linear combination of consumption and labor supply depends on the forecast of the discounted sum of future rental rates, wage rates, and productivity as well as current capital stock, productivity and market prices. We consider a symmetric equilibrium in what follows. To determine equilibrium prices and quantities, the learning model needs to be augmented by belief specification and updating presented in Section 4. The adaptive learning model has the same model equations. The different macroeconomic dynamics under AL relative to RE arises solely from different expectations in the consumption equation (3).
4 Learning about Long-Run Growth

Agents have imperfect knowledge of the long-run growth rates of endogenous variables and need to forecast wage rates and rental rates up to the indefinite future to make consumption decisions; see (3). They are assumed to have a simple econometric model, relating wages and the capital rental rate to the aggregate stock of capital

\[
\Delta \log R^K_t = \omega^r_0 + \omega^r_1 \Delta \log K_t + e^r_t \tag{4}
\]

\[
\Delta \log W_t = \omega^w_0 + \omega^w_1 \Delta \log K_t + e^w_t \tag{5}
\]

\[
\Delta \log K_{t+1} = \omega^k_0 + \omega^k_1 \Delta \log K_t + e^k_t, \tag{6}
\]

where \(e^r_t, e^w_t, \) and \(e^k_t\) are regression errors. We specify agents’ PLM directly in terms of levels (or differences) of the data. The beliefs have the same functional form as the linearized minimum-state-variable RE solution to the model (reformulated in levels). In the RE solution, \(\omega^r_0 = -\omega^r_1 \log \gamma, \omega^w_0 = (1 - \omega^w_1) \log \gamma, \omega^k_0 = (1 - \omega^k_1) \log \gamma, \omega^r_1 = \omega^r_1, \omega^w_1 = \omega^w_1, \omega^k_1 = \omega^k_1, e^r_t = -\omega^r_1 \hat{\gamma}_t, e^w_t = (1 - \omega^w_1) \hat{\gamma}_t, \) and \(e^k_t = (1 - \omega^k_1) \hat{\gamma}_t\) where bar coefficients denote RE values.

Let \(\omega^i_t = (\omega^i_0, \omega^i_1)\) for \(i = r, w, k\). \(z^r_t = \Delta \log R^K_t, z^w_t = \Delta \log W_t, z^k_t = \Delta \log K_{t+1}, \) and \(q_{t-1} = (1, \Delta \log K_t)\). Beliefs at period \(t\), \(\omega^i_t\) are updated recursively by the constant-gain Generalized Stochastic Gradient (GSG) learning algorithm as in Evans et al. (2010, henceforth EHW)

\[
\hat{\omega}^i_t = \hat{\omega}^i_{t-1} + g^i \Gamma q_{t-1} (z^i_t - \omega^i_{t-1} q_{t-1}) \tag{7}
\]

where \(\hat{\omega}^i_t\) denotes the current-period’s coefficient estimate. \(^{11}\) \(\Gamma\) controls the direction of belief

\(^{10}\)It can be shown that \(\overline{\omega}^r_1, \overline{\omega}^w_1, \) and \(\overline{\omega}^k_1\) are exactly the corresponding coefficients in the detrended and linearized RE solution for rental rates, wage rates and capital. We note that under RE the residuals in the perceived law of motion are correlated but that agents ignore possible correlations when estimating the forecast functions. This approach under AL is consistent with the standard approach in the literature; see eg. Eusepi and Preston (2011) and Sargent et al. (2009).

\(^{11}\)An alternative learning rule is the constant-gain recursive least squares (CG-RLS) algorithm. Online Appendix C4 shows that the impulse response functions of our model with CG-RLS learning are similar to the results with GSG learning. However, CG-RLS learning often imposes a projection facility on beliefs
updating and \( g^i \in (0, 1) \), the constant gain, determining the rate at which older observations are discounted. Bayesian and robustness justification for the GSG algorithm are provided in EHW. In particular, they show that (1) GSG learning algorithm asymptotically approximates the Bayesian optimal estimator when agents allow for drifting coefficients models, and (2) it is also the “maximally robust” estimator when agents allow for model uncertainty. As is standard in the literature, beliefs at \( t \) are updated using data up to period \( t - 1 \).

Analogous to (4) – (6), agents are assumed to have the following PLM for aggregate output and output per hour

\[
\Delta \log Y_t = \omega_0^p + \omega_1^p \Delta \log K_t + e_t^p \tag{8}
\]

\[
\Delta \log \left( \frac{Y_t}{H_t} \right) = \omega_0^pr + \omega_1^pr \Delta \log K_t + e_t^pr \tag{9}
\]

where \( e_t^p \) and \( e_t^pr \) are regression errors. They relate output and output per hour to capital as under RE. The forecast of long-run growth of output and output per hour are related to the forecast of the long-run growth of capital. They can be obtained by taking unconditional expectations of equations (6), (8), and (9) and combining the resulting equations; Online Appendix D1 provides the analytical formula.

\section{5 Quantitative Results}

This section evaluates the empirical performance of our learning model and contrasts it with that of the full-information RE model.

\subsection{5.1 Calibration}

The model is calibrated to the postwar US data. The business cycle data statistics are taken from Eusepi and Preston (2011) and their Appendix provides a description. The discount

and/or generates singularity problem in inverting the moment matrix; this is perhaps not fully desirable and we prefer presenting our results with GSG learning where the projection facility is not invoked.
factor $\tilde{\beta}$ is set to 0.99, the capital share $\alpha$ to 0.34, the depreciation rate $\delta$ to 0.025 and the unconditional mean of productivity growth $\bar{\gamma}$ to 1.0053. The inverse of Frisch elasticity of labor supply is 0.1. The standard deviation of productivity shock $\sigma_\gamma$ is calibrated to match the standard deviation of HP-filtered output volatility. The parameter $\sigma$ in the utility function is chosen to match the consumption growth volatilities and set to 1.9. Evidence on observed forecasts is used to discipline the choice of the gain parameter in line with Eusepi and Preston (2011). The gain parameters $g^k$ and $g^w$ are set to 0.014 and $g^r$ to 0.03. The larger gain parameter $g^r$ compared to $g^k$ and $g^w$ may be justified by the smaller measurement error (or larger signal-noise ratio) in interest rates vis-a-vis capital and wage rates.\(^{12}\) The moment matrix in (7) is set to the identity matrix, corresponding to the classical Stochastic Gradient (SG) algorithm.\(^{13}\) Online Appendix C presents the quantitative results to alternative values of the labor supply elasticity, gain parameter, moment matrices in the GSG learning rule and the constant-gain recursive least squares learning rule.

5.2 Impulse Response Functions

Figure 2 depicts the impulse response functions under RE and learning for 40 quarters in response to a 1% positive productivity shock. For stationary variables, percentage deviations from the steady state are plotted, while percentage deviations from the unshocked balanced growth path are reported for nonstationary variables. For the learning model, agents’ initial beliefs are set equal to the corresponding RE values, which yields identical impact response of the learning model as under RE.\(^{14}\)

\(^{12}\)Branch and Evans (2011) use heterogenous gain parameters in their learning model of stock market bubbles and crashes.

\(^{13}\)Adopting the Bayesian interpretation of the GSG algorithm, Evans et al. (2010), p. 240, indicate that the choice of the perceived parameter innovation covariance $V = \gamma^2 \sigma^2 M_z$ (in their notation) yields classical SG learning. They show that the SG learning algorithm is not scale invariant (pp. 260-261). This is because when they change the units of regressors, they do not change the corresponding prior of the perceived variance covariance matrix $V = \gamma^2 \sigma^2 M_z$. However, the prior should be suitably adjusted to $\tilde{V} = \gamma^2 \sigma^2 M_{\tilde{z}}$ in response to a change in the units of regressors. The quantitative results of our learning model are then scale invariant and remain exactly the same in response to a change in the units of regressors.

\(^{14}\)We note that the difference between median of the stationary distribution of agents’ beliefs and the corresponding RE values is very small. We use a relative measure i.e. median belief minus the corresponding
RE value divided by the RE value to measure this difference. This relative measure for the intercept term of the capital equation and rental rates equation are about 1%. And for the remaining four coefficients in agents’ PLM, this measure is smaller than 0.1%. The median and mean of the stationary distribution of the beliefs are also very close.
Figure 3: Response of forecasts of the discounted sum of wage and rental rates to a 1% positive productivity shock.

Figure 4. Learning model: responses of long-run (LR) growth forecasts and 1-quarter ahead forecast error (FE) to a 1% positive productivity shock.
Under RE, there is a shortfall of capital after the shock. This raises the marginal product of capital and hence the real interest rate. This implies the marginal utility of consumption must fall over time. Capacity utilization rises on impact due to the increase in rental rates. Output rises initially because working hours, capacity utilization and productivity increase initially. The high interest rates induce people to postpone their consumption and leisure and both variables increase over time. Output, on the other hand, decreases over time: this is because capacity utilization and working hours decrease over time and this is sufficiently pronounced to offset the effect on output from the rise in capital stock.

The improvements in the learning model arise from belief revisions and the interplay of beliefs and market outcomes. After the impact period, high realization of rental rates and wage rates leads to upward revisions of the forecasts for the discounted sum of wage and rental rates, as can be seen in Figure 3. The optimism about future wage rates helps to produce a further rise in consumption. Working hours increase as firms’ labor demand increases and the constant-consumption labor supply shifts rightward. The increase in the return to capital due to rising productivity and working hours induces an increase in investment. Output also rises due to increases in productivity, working hours, investment and capacity utilization. At some point, the realized wage rate growth falls short of their forecasts and they start revising their belief of wage rate growth downward. Associated with the downward belief revision is a decline in consumption and other aggregate activities. The mutual influence of agents’ expectations and equilibrium outcomes yields a decline in aggregate activities.

Rotemberg and Woodford (1996) demonstrated basic RE business cycle models (without variable utilization rates of capital) do not generate positive comovement between forecasted changes in consumption (C), investment (I), hours (H), and output (Y) present in the data. Our RE model with variable capacity utilization confirms the same finding in Figure 2. Under RE, output, investment and hours are falling while consumption is rising after impact, which produces negative comovement between forecasted changes in consumption and forecasted changes in the other three variables. In contrast, Figure 2 shows that there is positive
comovement between C, I, H and Y under learning after impact. Moreover, learning strongly amplifies the response of output, hours and investment and improves the internal propagation of the model evident in the persistent rise and fall of the four variables.

Figure 4 plots impulse response of long-run growth forecasts for output and output per hour on the top panel and 1-quarter ahead forecast error for output growth and rental rates in response to the productivity shock. The two long-run growth forecasts rise for several periods and then converge towards the RE value. Figures 2 and 4 suggest a positive correlation between long-run growth forecasts and cyclical activity. The 1-quarter ahead forecast errors – defined as the forecasts from the previous period minus the outturns – for output and rental rates become negative following the shock and are positively autocorrelated.

5.3 Statistical Properties

To compare with postwar US data, we calculate business cycle statistics based on 162 quarters. The learning model is simulated for 2000 + 162 periods and 500 repetitions. The first 2000 periods are used to generate the stationary distribution of beliefs and the final 162 periods are used to calculate the business cycle statistics. Median statistics are reported along with the standard deviations in the parenthesis. The learning model is stable and no projection facility is used in producing the statistics.

The long-run growth forecasts generated from the learning model share some common properties with the data; they display very persistent gaps between forecasts of long-run output growth (output per hour growth) and the corresponding HP-filtered trend growth estimates. Panel A of Table 2 reports the autocorrelation of the gaps for long-run output and output per hour growth. The learning model quantitatively matches well these autocorrelations in the data. The mutual influence of beliefs and market outcomes in the learning model also produces a positive correlation between forecasts of long-run output growth (or output per hour growth) and HP-filtered output, hours, consumption, and investment present in the data (refer to Panel B and C of Table 2). Short-term forecast errors for a wide range
of macroeconomic variables display a positive autocorrelation; see e.g. Eusepi and Preston (2011). Panel D shows that the learning model produces a positive autocorrelation of 1-quarter ahead forecast errors for GDP growth and real interest rate as in the data (albeit somewhat higher).

Table 3 reports major business cycle statistics. Recall that the standard deviation of the productivity shocks is chosen to match the HP-filtered output volatility in the data. This results in a standard deviation of productivity of 0.52% in the learning model and 0.99% in the RE model i.e. the learning model requires 47% smaller standard deviation of the productivity shocks. The standard deviation of hours and investment relative to output is 119% and 50% higher in the learning model and is closer to that in the data.

Burnside et al. (1996) reported 0.131 as the relative volatility of productivity shocks (measured by the Solow residuals associated with the US manufacturing sector during 1972-1992) to output after correcting for capital utilization, see their Table 1. This suggests a 70% drop in the volatility of the growth rate of productivity shocks relative to output than the number used in the basic RBC model; so a successful model must display much stronger amplification than the basic RBC model. Our learning model can produce strong amplification of productivity shocks; this ratio in the learning model is 0.143 and close to the BER estimate.\textsuperscript{15}

Panel B of Table 3 reports autocorrelation in the growth rates of C, I, Y, H and productivity. The RE model generates almost no propagation of the productivity shock; in particular, it does not generate the degree of autocorrelation of output growth present in the data as pointed out by Cogley and Nason (1995). As is evident from this table, a similar comment applies to the growth of C, I, H and productivity. The learning model generates strong propagation and produces somewhat higher autocorrelation of the growth rates data. The first-order autocorrelation of output growth is 0.48 in the learning model (in contrast to 0.30 in the data); this positive autocorrelation arises from belief revision and the interaction of beliefs and market outcomes evident in the impulse response functions in Figure 2. The learning model also generates strong propagation in other variables including labor productivity.

\textsuperscript{15}The counterpart to the total factor productivity (TFP) shocks in Burnside et al. (1996) in our model is $(1 - \alpha)\gamma_t$ with $\alpha = 0.34$. The standard deviation of the growth rate of productivity shocks and output in our model is 0.52% and 3.62%/4. So the ratio of the volatility of the growth of TFP to output is $(1 - 0.34)^2 \frac{(0.52\%)^2}{(3.62%/4)^2} = 0.143.$
Panel C and D report the business cycle statistics using data on growth rates. The learning model delivers a good fit to the volatility of output growth and other relative standard deviations, such as investment and hours growth volatilities. It also generates significantly better correlation between productivity growth and output growth \( \rho_{\Delta Pr, \Delta Y} \) and between productivity growth and hours growth \( \rho_{\Delta Pr, \Delta H} \).\(^{16}\)

### 6 Knowledge about Long-Run Growth in RE Models

This section shows existing full-information and imperfect information RE models cannot produce the facts reported in sections 2.1 and 2.2. The productivity process (2) is augmented as

\[
\log\left(\frac{X_t}{X_{t-1}}\right) = \log(\gamma_t) + \hat{\gamma}_t \quad (10)
\]

\[
\log(\gamma_t) = (1 - \rho_\gamma) \log(\gamma) + \rho_\gamma \log(\gamma_{t-1}) + \hat{\gamma}_t. \quad (11)
\]

\(\rho_\gamma\) is in \((-1, 1]\), \(\hat{\gamma}_t\) are i.i.d shocks to trend growth rates and \(\log(\gamma)\) is the unconditional mean of the trend growth rates. Most RE models assume \(\rho_\gamma = 0\) and \(\hat{\gamma}_t = 0\) which reduces to our process (2) eg. King and Rebelo (1999). The formulation (10)-(11) allows for time-varying and persistent trend growth rates as in e.g. Aguiar and Gopinath (2007) and Edge et al. (2007).

Section 6.1 (Section 6.2) shows that existing full information and imperfect information RE models with \(|\rho_\gamma| < 1\) (\(\rho_\gamma = 1\)) produce counterfactually zero (negative) correlation between long-run growth forecasts and cyclical activity, which is inconsistent with the evidence in Section 2.2.

\(^{16}\)Online Appendix D2 reports correlations of HP-filtered data and Appendix C shows that the quantitative results are robust to alternative parameterizations of the model and learning rules.
6.1 Mean-Reverting Trend Growth \(||\rho_\gamma|| < 1\)

In full-information models e.g., Aguiar and Gopinath (2007), agents can observe productivity growth and its trend component. They have sufficient information – such as the knowledge of other agents’ beliefs, preferences and technology – to derive the equilibrium mapping from the trend growth of exogenous variables (e.g. productivity) to the trend growth of endogenous variables (e.g. output, output per hour); they know exactly the law of motion for endogenous variables and their long-run growth rates. These RE models (with or without time-varying trend growth) are inconsistent with the facts documented in Section 2.1 and 2.2 because (1) agents’ long-run output (and output per hour) growth forecasts are constant \((\log(\gamma))\) and do not display persistent gaps with respect to the actual long-run growth, (2) the correlation between long-run growth forecasts and cyclical activity is zero.\(^{17}\)

Another class of models assume agents have less information and cannot observe the trend growth rates of the exogenous (productivity) process, such as Edge et al. (2007) and Boz et al. (2011). Agents face a signal extraction problem; they use the new observation of productivity to update their trend growth beliefs. However, agents in these models are endowed with the knowledge of \(\rho_\gamma\) and \(\log(\gamma)\), so their long-run productivity growth forecasts are constant \((\log(\gamma))\) over time. Since agents know the equilibrium mapping from long-run productivity growth to long-run output (and output per hour) growth, all these growth forecasts are equal to \(\log(\gamma)\). These models also produce zero correlation between long-run output (or output per hour) growth forecasts and cyclical activity. Moreover, as a consequence of RE, the gaps between long-run growth forecasts and actual long-run growth will not display a systematic pattern, which is inconsistent with the evidence in Section 2.1.

\(^{17}\)These comments also apply to full-information RE models which do not explicitly model the trend component but start directly with detrended variables (or the cyclical component). This is because implicitly, agents in these models also have exact knowledge about the law of motion for the trend.
6.2 Random Walk Trend Growth ($\rho_{\gamma} = 1$)

We now show that in the case $\rho_{\gamma} = 1$ (e.g. considered in Edge et al., 2007), full-information and imperfect information RE models produce a negative correlation between forecasts of long-run output (or output per hour) growth and cyclical activity. Agents update their trend growth beliefs via a constant-gain learning rule (or equivalently the Kalman filter with steady state updating coefficients)

$$\log(\tilde{\gamma}_t) = \log(\tilde{\gamma}_{t-1}) + g^x \left( \log \left( \frac{X_t}{X_{t-1}} \right) - \log(\tilde{\gamma}_{t-1}) \right).$$

Economic decisions are based on their beliefs about the trend productivity growth.

For illustration, the gain parameter $g^x$ is set to $0.11/4$ as in Edge et al. (2007). The standard deviation of $\hat{\gamma}_t$ is set to 0.52% as in our adaptive learning model; the standard deviation of the shock to long-run growth rate is set to 0.015% implied by the chosen gain. All other parameters are identical to those in our benchmark setting. (Similar shapes of IRFs are found for alternative values of gain parameters.) The long-run growth forecasts for productivity, output and output per hour are the same due to agents’ exact knowledge of the equilibrium mapping.

Figure 5 reports the response of detrended variables (measured as percentage deviations from the steady state) and the annualized long-run growth forecasts to a positive 1% shock to the level of productivity. The full-information model is labeled “REF” and the imperfect information model is labeled “REL”. The REF model produces constant long-run growth forecasts and zero correlation between the forecasts and detrended variables; the level shock does not change long-run growth forecasts. In the REL model, long-run growth forecasts are not constant. The positive shock leads to an upward revision of the long-run growth forecasts. The impact response of $Y$, $I$, $C$, and $H$ are smaller in the REL model relative to REF due to higher long-run growth expectations and larger wealth effects on leisure. Associated with a rise in the long-run growth forecasts is a decline in $Y$, $I$, $C$, and $H$. After the impact period, agents revise their long-run growth forecasts down. Associated with this downward belief revision is rising $Y$, $I$, $C$, and $H$. This suggests negative comovement between long-run growth forecasts and detrended macro variables.
Our adaptive learning model is better able to reproduce the relevant business cycle volatilities than the REL model mainly due to the feedback from market outcomes to agents’ beliefs. Comparing Figure 2 with Figure 5, the amplitude of the response of output, investment, and hours in our adaptive learning model is 54%, 90% and 108% larger than the corresponding numbers of the REL model.

Figure 5: Response to a 1% positive shock to the productivity level
Figure 6 displays the response to a positive one standard deviation shock to trend productivity growth. Under REF, (detrended) $Y$, $I$, $C$, $H$ decline a lot due to the large wealth effects in the impact period, while long-run growth forecasts increase on impact. The forecasts stay constant afterwards associated with which are rising $Y$, $I$, $C$, $H$. Again these suggest a negative correlation between long-run growth forecasts and detrended variables.

Under REL, long-run growth forecasts increase much less initially relative to REF and as a consequence, cyclical aggregate activities decline by less. There is negative comovement between the long-run growth forecasts and detrended variables.

Before concluding this section, we remark that shocks to trend productivity growth, as eg. in (10)-(11), are not required by our learning model (presented in Section 4) to generate the high autocorrelation in trend growth rates of output and output per hour evidenced in the data. Our model with zero correlation in trend productivity growth *endogenously* generates an autocorrelation coefficient of 0.99 and 0.996 for trend output growth and trend output per hour growth respectively, using HP-filtering; the corresponding numbers in the data are 0.99 and 0.984 (see e.g. Figure 1).
7 Adaptive Learning (AL) Models

This section shows that the belief specification in existing AL business cycle models imply that agents have exact knowledge of the trend growth of endogenous variables (as under RE). Therefore, these models produce constant long-run growth forecasts and zero correlation between long-run growth forecasts and cyclical activity, which appear inconsistent with the observed forecasts.

AL modelers make weaker informational assumptions with agents having incomplete knowledge of the structure of the economy analyzing macroeconomic policy and their empirical implications, such as Bullard and Mitra (2002), Evans and Honkapohja (2003), and Eusepi and Preston (2011). These models assume agents only learn detrended variables and typically the parameter coefficients in the detrended and linearized RE solution. Take the following perceived law of motion (PLM) as an example

\[
\begin{align*}
\hat{R}_t^K &= \omega_0^r + \omega_1^r \hat{k}_t + \omega_3^r \hat{\gamma}_t + e_t^r, \\
\hat{w}_t &= \omega_0^w + \omega_1^w \hat{k}_t + \omega_3^w \hat{\gamma}_t + e_t^w, \\
\hat{k}_{t+1} &= \omega_0^k + \omega_1^k \hat{k}_t + \omega_3^k \hat{\gamma}_t + e_t^k;
\end{align*}
\]

(12) (13) (14)

\(\omega's\) are agents’ belief parameters and \(e_t^r, e_t^w, \text{ and } e_t^k\) are regression errors.\(^{18}\) Under RE, \(\omega_0^r = \omega_0^w = \omega_0^k = 0\) and \(e_t^r = e_t^w = e_t^k = 0; \omega_1's\) and \(\omega_3's\) are RE coefficients. Under adaptive learning, agents are uncertain and learn about \(\omega's.\) The intercept terms in (12)-(14) can be interpreted as agents’ uncertainty about the non-stochastic steady state or the level of the trend component (in contrast to exact knowledge of the level of the trend under RE).

We reformulate (12)-(14) in levels and perform the Beveridge and Nelson (1981) decomposition for log rental rates, wage rates, and capital. \(\log Z_t^P\) denotes the trend component of variable \(\log Z_t.\)

\(^{18}\)Eusepi and Preston (2011) and Huang et al. (2011) use similar formulations; the latter assumes that agents only learn about the steady state of capital i.e. \(\omega_1^k = \omega_3^k = 0.\)
Proposition 1. The belief specification (12)-(14) implies that households’ perceived law of motion for the trend component of log rental rates, wage rates, and capital are

\[
\log(R^K_t)^P - \log(R^K_{t-1})^P = 0 \quad (15)
\]

\[
\log W_t^P - \log W_{t-1}^P = \log \gamma + \hat{\gamma}_t \quad (16)
\]

\[
\log K_{t+1}^P - \log K_t^P = \log \gamma + \hat{\gamma}_t \quad (17)
\]

Online Appendix E provides the proof. Agents know exactly the trend growth rate of rental rates, wage rates, and capital, including not only the deterministic but also the stochastic component. The growth component of trend wage rates and capital, i.e., the right hand sides of (16) and (17), are identical to the growth component of the productivity process, i.e., the right hand side of (2). To emphasize, they know that the unconditional mean growth rate of wages and capital is identical to that of the productivity process. Moreover, they also know precisely how a shock to the productivity \(\hat{\gamma}_t\) affects the evolution of the permanent component of wages and capital (i.e. they know that the coefficient of \(\hat{\gamma}_t\) is 1!). The growth component of rental rates, i.e., the right hand side of (15) is zero; this implies that agents know that the permanent component \(\log(R^K_t)^P\) is constant over time and hence that \(\log(R^K_t)\) is stationary. Beyond knowing that some endogenous variables are stationary and that the rest non-stationary, the belief specification (12)-(14) implies that agents know the existence of a balanced growth path. In particular, agents are aware that the non-stationary variables share a common trend which is equal to the growth rate of productivity.\(^{19}\) Online Appendix F provides a graphic illustration on how our learning model is conceptually different from the formulation of learning with detrended data and with the full-information RE benchmark.

\(^{19}\)The same arguments apply to models with under-parameterized PLMs, e.g. Huang et al. (2011) (see also Adam (2007) for an under-paramterized PLM in a sticky price model). The arguments also apply to AL models with over-parameterized PLMs and to Bullard and Duffy (2005) and Mitra et al. (2013) where agents learn the law of motion of (detrended) linearized variables rather than percentage deviations from the non-stochastic steady state; see the proof in Online Appendix E.
(and output per hour) growth forecasts in these AL models will be constant, i.e., \( \log(\gamma) \) and not correlated with cyclical activity.

8 Conclusion

Macroeconomic models used for analyzing economic fluctuations and welfare separate an underlying growth path or trend from the cycle and assume agents have exact knowledge of the law of motion for the trend component of endogenous variables including their long-run growth. These models produce zero correlation between long-run growth forecasts and cyclical activity and do not generate persistent gaps between long-run growth forecasts and the corresponding actual long-run growth. These implications are inconsistent with observed forecasts which suggest a positive correlation between the long-run output (or output per hour) growth forecasts and cyclical activity and strong positive autocorrelation of gaps between forecasts of long-run output growth (output per hour growth) and the corresponding HP-filtered trend growth estimate. A simple RBC model with learning about the long-run growth rate of endogenous variables is developed. This model can produce these positive correlations and suggests that optimism and pessimism about long-run growth rates is a crucial ingredient in understanding business cycle fluctuations.

References

A Forecast Properties: Data

Using SPF data, Table A.1 reports the correlation between expectations of long-run output growth and detrended output, consumption, investment and hours; robust p-values are reported in parenthesis. As mentioned in the text there continues to be a strong positive correlation between long-run output growth forecasts and detrended variables. Most of the robust p-values are no more than 1%.

Tables A.2, A.3 and A.4 report the correlation between expectations of long-run output per hour growth and detrended variables using CBO, CEA, and SPF data as well as the corresponding robust p-values. These measures are strongly positive and robust to three sources of forecasts and different detrending methods. All the correlations are statistically significant at the 5% level for SPF forecasts and the majority of them are significant at the same level for CEA and CBO forecasts. Unfortunately, we are handicapped by the lack of data as far as obtaining significance is concerned; see also footnote 4 in the text.

The short term forecast errors for a wide range of macroeconomic variables display a similar systematic pattern documented in e.g., Eusepi and Preston (2011). They show, for example, the median agent tends to under-predict interest rates and overpredict unemployment over expansions, and contrariwise during contractions. Figure A.1 shows that the median agent tends to under-predict real output growth over expansions and contrariwise during contractions using 1-quarter ahead forecast data. Table A.5 reports the autocorrelation of median 1-quarter forecast errors for real GDP growth, two measures of interest rates,
and unemployment, all of which display a positive correlation.\textsuperscript{20}

\section*{B Model Details}

This section provides first-order conditions, the steady state and log-linearizations of the model. The variables with a bar are the non-stochastic steady state values while the variables with a hat denote log-linearized variables around the non-stochastic steady state i.e. $x_t = \log \hat{X}_t$. Capital letters denote levels while small case letters denote their stationary counterparts.

Household optimization yields the following first-order conditions:

\begin{align*}
C_t & : u_C(C_t, L_t) = \Lambda_t \\
K_{t+1} & : \beta \hat{E}_t \Lambda_{t+1} R^K_{t+1} U_{t+1} - \Lambda_t + \beta \hat{E}_t [\Lambda_{t+1}(1 - \delta(U_{t+1}))] = 0 \\
L_t & : u_L(C_t, L_t) = \Lambda_t W_t \\
U_t & : R^K_t = \delta'(U_t)
\end{align*}

where $\Lambda_t$ is the Lagrangian multiplier associated with period $t$ budget constraint.

\textit{Steady State}

From the consumption Euler equation we get

\[
\frac{R^K_U}{\gamma} = \gamma^{\sigma - 1} \beta^{1 - \frac{1 - \delta}{\gamma}} = \beta^{-1} - \frac{1 - \delta}{\gamma}
\]

\textsuperscript{20}Using real time data, the autocorrelation of errors in 1, 2, 3 and 4-quarter-ahead real GDP growth forecasts are 0.23, 0.35, 0.36 and 0.38.
and from the capacity utilization first-order condition

\[
\frac{\Pi^k U}{\gamma} = \frac{\delta \theta}{\gamma} => \theta = \frac{\Pi^k U}{\delta}
\]

which defines \( \theta \), allowing to determine \( U \) and therefore \( R^k \). The ratios

\[
\frac{\gamma}{k} = (\alpha)^{-1} \frac{R^k U}{\gamma}; \frac{\bar{i}}{k} = 1 - \frac{1}{\gamma} \frac{\gamma}{k}; \frac{\bar{c}}{k} = \frac{\bar{y}}{k} - \frac{\bar{i}}{k} \text{ and } \frac{\bar{c}}{\bar{y}} = \frac{\bar{c}}{k} / \frac{\bar{y}}{k}
\]

Finally the steady state level \( \psi \), for a given choice of \( \bar{H} \), is determined by

\[
\psi = \frac{\bar{H} v'(\bar{H})}{v(\bar{H})} (\sigma - 1)^{-1} = \frac{\bar{w} \bar{H} \bar{y}}{\bar{c}} = (1 - \alpha) \frac{\bar{y}}{\bar{c}}
\]

**Equilibrium condition and log-linearization**

Households' optimality conditions

1. Marginal utility of consumption

\[
\hat{\lambda}_t = -\sigma \hat{c}_t - \psi (1 - \sigma) \hat{H}_t
\]

where in steady state

\[
\psi \equiv -\frac{\bar{H} v'(\bar{H})}{v(\bar{H})} (1 - \sigma)^{-1} = \frac{\bar{w} \bar{H}}{\bar{c}}
\]

2. Euler equation

\[
\beta \hat{E}_t [\beta^{-1} (\hat{\lambda}_{t+1} - \hat{\lambda}_t - \sigma \hat{\gamma}_{t+1}) + (\beta^{-1} - \frac{1 - \delta}{\gamma}) (\hat{R}_{t+1} + \hat{U}_{t+1}) - \frac{\delta}{\gamma} \theta \hat{U}_{t+1}] = 0
\]
Substituting the steady-state relation into the above equation yields

\[
\frac{R^K U}{\gamma} = \left( \beta^{-1} - \frac{1}{\gamma^\sigma} \right) = \frac{\theta \delta}{\gamma}
\]

becomes

\[
\beta \hat{E}_t \left[ \beta^{-1}(\hat{\lambda}_{t+1} - \hat{\lambda}_t - \sigma \hat{\gamma}_{t+1}) + (\beta^{-1} - \frac{1}{\gamma^\sigma}) \hat{R}^K_{t+1} \right] = 0 \tag{19}
\]

3. Labor-leisure choice:

\[
(1 - \sigma) \hat{c}_t + \epsilon_v \hat{H}_t = \hat{\lambda}_t + \hat{w}_t
\]

which, combined with the expression for marginal utility, gives:

\[
\sigma^{-1} \hat{\lambda}_t + \hat{w}_t = \epsilon_H \hat{H}_t \tag{20}
\]

where

\[
\epsilon_H = \epsilon_v - \frac{(\sigma - 1)^2}{\sigma} \psi > 0
\]

is the inverse Frisch elasticity of labor supply.

4. Capacity utilization

\[
\hat{U}_t = \frac{\hat{R}^K_t}{\theta - 1}
\]

Using the expression for the marginal utility of consumption, the Euler equation becomes

\[
\hat{\lambda}_t = \hat{E}_t \left[ (\hat{\lambda}_{t+1} - \sigma \hat{\gamma}_{t+1}) + \beta \hat{R}^K_{t+1} \right] - \sigma \hat{c}_t - (1 - \sigma) \hat{H}_t = \hat{E}_t \left[ -\sigma \hat{c}_{t+1} - (1 - \sigma) \hat{H}_{t+1} \right] - \sigma \hat{E}_t \hat{\gamma}_{t+1} + \hat{E}_t \beta \hat{R}^K_{t+1}
\]
where
\[
\bar{R} = \left( \beta^{-1} - \frac{1 - \delta}{\gamma} \right)
\]

\textit{Firms’ problem}

The firms’ problem is
\[
\max_{U_tK_t, H_t} Y_t - W_tH_t - R_t^K (U_tK_t)
\]
subject to the production technology
\[
Y_t = (U_tK_t)^\alpha (X_t H_t)^{1-\alpha}
\]
The first order condition with respect to hours:
\[
-W_t + (1 - \alpha) (U_tK_t)^\alpha (X_t)^{1-\alpha} H_t^{-\alpha} = 0
\]
becomes
\[
(1 - \alpha) X_{t-1}^\alpha \left( \frac{U_t K_t}{X_{t-1}} \right)^\alpha X_t^{-\alpha} = 0
\]
and hence
\[
(1 - \alpha) \gamma_t^{-\alpha} (U_t k_t)^\alpha H_t^{-\alpha} = w_t
\]
Combined with the definition of output gives
\[
w_t = (1 - \alpha) \frac{y_t}{H_t}
\]
which in log-linear form becomes

\[ \hat{w}_t = \hat{y}_t - \hat{H}_t \]  

(21)

The capital input decision gives:

\[
0 = -R^K_t + \alpha(U_t K_t)^{\alpha-1}(X_t H_t)^{1-\alpha}
\]

\[
= -R^K_t + \alpha(U_t K_t)^{\alpha-1}(H_t)^{1-\alpha}
\]

\[
= -R^K_t + \alpha(U_t k_t)^{\alpha-1}(H_t)^{1-\alpha}
\]

Using the definition of output yields

\[
R^K_t = \alpha \gamma_t \frac{y_t}{U_t k_t}
\]

which in log-linear form is

\[ \hat{R}_t^K = \hat{\gamma}_t + \hat{y}_t - \hat{U}_t - \hat{k}_t \]

Finally, the evolution of capital is

\[ K_{t+1} = (1 - \delta) K_t + I_t \]

The log-linearized version is

\[ \hat{k}_{t+1} = \hat{k}_t + \frac{1 - \delta}{\hat{\gamma}} \left( \hat{k}_t - \hat{\gamma}_t \right) - \frac{\delta \theta}{\hat{\gamma}} \hat{U}_t \]
Market clearing requires

\[ Y_t = C_t + I_t \]

The log-linearized version is

\[ \hat{y}_t = \left(1 - \frac{\sigma}{\theta} \right) \hat{i}_t + \frac{\sigma}{\theta} \hat{c}_t \]

To summarize, the system of log-linearized equations under RE is

\[
\begin{align*}
\hat{w}_t &- \left( \epsilon_H - \frac{\sigma - 1}{\sigma} \psi \right) \hat{H}_t - \hat{c}_t = 0 \\
- \hat{w}_t + \hat{y}_t - \hat{H}_t & = 0 \\
- \hat{R}_t^K + \hat{y}_t - \hat{U}_t - \left( \hat{k}_t - \hat{\gamma}_t \right) & = 0 \\
- \hat{y}_t + \left(1 - \frac{\sigma}{\theta} \right) \hat{i}_t + \frac{\sigma}{\theta} \hat{c}_t & = 0 \\
- \hat{y}_t + (1 - \alpha) \hat{H}_t + \alpha \hat{U}_t + \alpha \left( \hat{k}_t - \hat{\gamma}_t \right) & = 0 \\
- \frac{\delta \theta}{\theta} \hat{U}_t - \hat{k}_{t+1} + \frac{\tau}{\theta} \hat{c}_t + \frac{(1 - \delta)}{\theta} \left( \hat{k}_t - \hat{\gamma}_t \right) & = 0 \\
- \frac{\hat{R}_t^K}{\theta - 1} + \hat{U}_t & = 0 \\
(\sigma \hat{c}_t + (1 - \sigma) \hat{H}_t) - \hat{E}_t[(\sigma \hat{c}_{t+1} + (1 - \sigma) \hat{H}_{t+1}) - \sigma \hat{\gamma}_{t+1}) + \beta R \hat{R}_{t+1}^K & = 0
\end{align*}
\]

**Consumption Decision Rule**

In our learning model, the last equation in the above system is replaced by the following consumption decision rule.
\[
\tilde{c}_t + \sigma^{-1}\psi(1 - \sigma)\tilde{H}_t = \frac{(1 - \chi)(1 - \tilde{\beta})}{\varepsilon_c} \left[ \tilde{\beta}^{-1} \hat{k}_t + \tilde{R}\hat{R}_t^K - \tilde{\beta}^{-1} \hat{\gamma}_t + \left( \varepsilon_w + \varepsilon_c \frac{\chi}{1 - \chi} \right) \hat{w}_t \right] \\
+ \tilde{E}_t \sum_{T=t}^{\infty} \tilde{\beta}^{T-t} \Delta_1 \tilde{R}_{T+1} + \tilde{E}_t \sum_{T=t}^{\infty} \tilde{\beta}^{T-t} \Delta_2 \tilde{w}_{T+1},
\]

which is identical to the last equation of page 7 in the Online Appendix of Eusepi and Preston (2011) with \(\Delta_1 = \left[ \frac{(1 - \chi)(1 - \tilde{\beta})}{\varepsilon_c} - \tilde{\beta}\sigma^{-1} \right] \tilde{R} \) and \(\Delta_2 = \frac{(1 - \chi)(1 - \tilde{\beta})}{\varepsilon_c} \tilde{\beta} \left( \varepsilon_w + \varepsilon_c \frac{\chi}{1 - \chi} \right) \).

Derivations and the definition of composite parameters \(\psi, \chi, \tilde{\beta}, \tilde{R}, \varepsilon_w, \varepsilon_c\) are provided there.

## C Robustness

This section provides robustness analysis of our model with alternative values of gain parameters, labor supply elasticity, alternative moment matrices in the GSG learning algorithm and the constant gain recursive least squares (RLS) learning algorithm.\(^{22}\) In this section, the standard deviation of the productivity shock in both the RE and our learning model are set equal to 0.52\% (as in our baseline learning model). As in the baseline learning model, the projection facility is not used in generating statistics in this section.

### C.1 Alternative gain parameters

Table A.6 demonstrates the empirical performance of the learning model under alternative gain parameters spanning the interval \((0.006, 0.017)\) for \(g^w\) and \(g^k\) and \((0.017, 0.036)\) for \(g^r\).

---

\(^{21}\)Except that, for the sake of economy, the forecast of the discounted sum of productivity in the corresponding equation of Eusepi and Preston (2011) is zero and dropped due to the i.i.d. assumption for productivity shocks.

\(^{22}\)Statistics not reported in the tables here are available upon request.
Recall our baseline learning model has the gain parameter $g^w = g^k = 0.014$ and $g^r = 0.03$.

The first rows $Y^{TG}$ reports the autocorrelation of gaps between forecasts of long-run output growth and HP-filtered output growth, while the second row $(Y/H)^{TG}$ reports the corresponding autocorrelation for output per hour. Row 3-4 show the autocorrelation of one-period ahead forecast errors for rental rates ($\rho^{RE}$) and output growth ($\rho^Y$). Panel B (Panel C) reports the correlation between long-run output (output per hour) growth forecasts and HP-filtered data. The results of the learning model with alternative gain parameters are robust and continue to be consistent with the evidence in observed forecasts.

We define a measure of the degree of amplification of our learning model relative to RE, $X_{\text{dif}}$, as follows

$$X_{\text{dif}} = \frac{X^{\text{Learn}} - X^{RE}}{X^{RE}}$$

where $X = \sigma_Y, \sigma_I/\sigma_Y, \sigma_H/\sigma_Y$ and $X^{\text{Learn}}$ is the relevant variable under our learning model and similarly $X^{RE}$ under RE. Recall $\sigma_Y$ is the HP-filtered output standard deviation, $\sigma_I/\sigma_Y$ is the relative standard deviation of investment to output and $\sigma_H/\sigma_Y$ is the relative standard deviation of working hours to output. $X_{\text{dif}}$ are reported in the first three rows of Panel D and the first-order autocorrelation of output growth is used to measure propagation and reported in the fourth row. Simulation results show that these statistics are robust with respect to alternative gain parameters.

### C.2 Alternative labor supply elasticities

Table A.7 reports the statistics of the learning and RE model with lower labor supply elasticities $\epsilon^{-1}_H = 2$ or 7. The correlation between long-run output per hour growth and detrended
variables are very close to the corresponding numbers when long-run output growth forecasts are used and hence not reported here and in the next section.

With labor supply elasticity of 7, the empirical performance of the learning model is quantitatively similar to the baseline case. When labor supply elasticity is set to 2, the learning model generates 30%, 51% and 133% larger standard deviation for output, investment and hours relative to the RE model. While the learning model remains consistent with observed forecasts, it does not generate the positive serial correlation in consumption growth.

C.3 Alternative Moment Matrices

Recall in the baseline model, the moment matrix $\Gamma$ is set to the identity matrix, corresponding to the classical Stochastic Gradient (SG) learning. This section considers alternative moment matrices $\Gamma$ which change the direction of belief updating in different ways. Adopting the Bayesian interpretation of the GSG algorithm, the alternative matrices imply increasing the prior precisions of the perceived innovations to the regressor capital growth. Table A.8 and Table A.9 display the performance of our learning model with other alternative moment matrices $\Gamma_1 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, $\Gamma_2 = \begin{pmatrix} 1 & 0 \\ 0 & 0.05^2 \end{pmatrix}$, $\Gamma_3 = \begin{pmatrix} 1 & 0.1 \\ 0.1 & 1 \end{pmatrix}$, $\Gamma_4 = M_z^{-0.5}$, and $\Gamma_5 = M_z^{-0.7}$ where $\Gamma = \Gamma_i$, $i = 1, 2, \ldots, 5$ and $M_z$ is the asymptotic second moment matrix.

Our learning model with $\Gamma = \begin{pmatrix} 1 & 0 \\ 0 & 0.5^2 \end{pmatrix}$ produces identical results (up to two decimals) as in the baseline case; hence it is not shown in the table. The quantitative results of the learning model remain exactly the same in response to a change in the units of regressors; see footnote 12.

Page 27 of Evans, Honkapohja and Williams (2005) shows that $\Gamma_4$ can be obtained by having the parameter innovation covariance matrix $V = \gamma^2 \sigma^2 I$. Agents then perceive the innovation to the intercept and coefficient of capital growth are independent of each other.

---

23 The quantitative results of our learning model remain exactly the same in response to a change in the units of regressors; see footnote 12.

24 Page 27 of Evans, Honkapohja and Williams (2005) shows that $\Gamma_4$ can be obtained by having the parameter innovation covariance matrix $V = \gamma^2 \sigma^2 I$. Agents then perceive the innovation to the intercept and coefficient of capital growth are independent of each other.
learning model are robust with respect to these alternative choices of the moment matrix.

C.4 Impulse Response Functions under Recursive Least Squares Learning

This section shows the impulse response functions (IRFs) of our learning model under the constant gain recursive least squares learning (CG-RLS) algorithm are similar to the baseline of GSG learning presented in the text. For illustration, the parameters are identical to our baseline model except that the gain parameters for the CG-RLS learning are $g^w = g^k = 0.005$, $g^r = 0.016$. The gain parameter for updating the moment matrix is also set to 0.005.

Figure A.2 displays the IRFs of our learning model with CG-RLS learning. There is a positive correlation between long-run output (or output per hour) growth forecasts and cyclical activity. In addition, learning produces the positive comovement of consumption and hours, amplifies the response of Y, C, I, H and improves the internal propagation of the business cycle model. The responses are quantitatively similar to those in the baseline model with GSG learning.
D Additional Results

D.1 Calculation of Long-Run Growth Forecasts

In the paper, agents are assumed to have the following PLM for aggregate output and output per hour

\[ \Delta \log Y_t = \omega_y^0 + \omega_y^1 \Delta \log K_t + e_y^t \]
\[ \Delta \log \left( \frac{Y_t}{H_t} \right) = \omega_{pr}^0 + \omega_{pr}^1 \Delta \log K_t + e_{pr}^t \]

where \( e_y^t \) and \( e_{pr}^t \) are regression errors. They relate output growth and output per hour growth to capital growth as under RE.

Agents’ take unconditional expectations of the PLM for capital and output or output per hour to calculate the forecast of long-run growth of real GDP, \( Y^{TG} \), and output per hour, \( (Y/H)^{TG} \), as follows

\[ Y^{TG} = \omega_y^0 + \omega_y^1 \frac{\omega_k^0}{1 - \omega_k^1} \]
\[ (Y/H)^{TG} = \omega_{pr}^0 + \omega_{pr}^1 \frac{\omega_k^0}{1 - \omega_k^1} \]

The long-run growth forecasts of output and output per hour depend on the forecast of long-run growth of aggregate capital.
D.2 Additional Business Cycle statistics

Table A.10 reports the correlation of HP-filtered data in our benchmark learning model along with the standard deviations.

E Proof of Proposition 1

We now derive agents’ perceived law of motion for the trend component of log rental rates, wage rates, and capital. Agents’ perceived law of motion is

\[ \hat{R}_t^K = \omega_r^0 + \omega_r^1 \hat{k}_t + \omega_r^3 \hat{\gamma}_t + e_t^r, \] (23)

\[ \hat{w}_t = \omega_w^0 + \omega_w^1 \hat{k}_t + \omega_w^3 \hat{\gamma}_t + e_t^w, \] (24)

\[ \hat{k}_{t+1} = \omega_k^0 + \omega_k^1 \hat{k}_t + \omega_k^3 \hat{\gamma}_t + e_t^k, \] (25)

Recall the productivity process follows

\[ \log X_{t+1} = \log X_t + \log \gamma + \hat{\gamma}_{t+1} \]

where \( \hat{\gamma}_{t+1} \) is an i.i.d process. We have

\[ \Delta \log X_t = \log \gamma + \hat{\gamma}_t \] (26)

Lagging the above equation by one period delivers

\[ \Delta \log X_{t-1} = \log \gamma + \hat{\gamma}_{t-1} \] (27)
The definitions of log-linearized variables are

\[ \hat{k}_{t+1} = \log k_{t+1} - \log \bar{k} \] (28)
\[ \hat{w}_t = \log w_t - \log \bar{w} \] (29)
\[ \hat{R}_t^K = \log R_t^K - \log \bar{R}_K \] (30)

Substituting \( \hat{k}_{t+1} \) and \( \hat{k}_t \) using (28) into (25) and differencing, we get\(^{25}\)

\[ \Delta \log k_{t+1} = w_1^k \Delta \log k_t + w_3^k \Delta \hat{\gamma}_t + \Delta e_t^k \]

Lagging the above equation by one period yields

\[ \Delta \log k_t = w_1^k \Delta \log k_{t-1} + w_3^k \Delta \hat{\gamma}_{t-1} + \Delta e_{t-1}^k \] (31)

Denote by \( L \) the lag operator. Equation (31) can be transformed to

\[ \Delta \log k_t = \frac{(1 - L) \left( w_3^k \hat{\gamma}_{t-1} + e_{t-1}^k \right)}{1 - w_1^k L} \] (32)

The data are detrended as follows

\[ k_t = \frac{K_t}{X_{t-1}} \]
\[ w_t = \frac{W_t}{X_t} \]

\(^{25}\)In accordance with the “Anticipated Utility Approach” of Kreps (1998) adopted by adaptive learning models, we assume that agents believe the \( \omega \)'s are constant; see Cogley and Sargent (2008) for a discussion.
or equivalently we have

$$\log K_t = \log k_t + \log X_{t-1}$$

$$\log W_t = \log w_t + \log X_t$$

Differencing the above two equations, we get

$$\Delta \log K_t = \Delta \log k_t + \Delta \log X_{t-1} \quad (33)$$

$$\Delta \log W_t = \Delta \log w_t + \Delta \log X_t \quad (34)$$

Combining (27), (32), and (33), we get

$$\Delta \log K_t = \Delta \log k_t + \Delta \log X_{t-1}$$

$$= \frac{(1 - L) \left( w_3^k \gamma_{t-1} + e_{t-1}^k \right)}{1 - w_1^k L} + \log \gamma + \hat{\gamma}_{t-1}$$

By redefining $G_t = K_{t+1}$, the above equation becomes

$$\Delta \log G_t = \frac{(1 - L) \left( w_3^k \gamma_t + e_t^k \right)}{1 - w_1^k L} + \log \gamma + \hat{\gamma}_t$$

According to the Theorem on page 29 of Granger and Newbold (1986), the sum of two independent MA(1) processes $(1 - L) \left( w_3^k \gamma_t + e_t^k \right)$ is still an MA(1) process.

The BN decomposition\(^{26}\) for an ARIMA process here follows page 51 of Favero (2001).

\(^{26}\)The idea of the BN decomposition of a linear ARIMA process is as follows. For a time series $z_t$, suppose agents make conditional forecasts for $z$ given data up to date $t$. When time goes to positive infinity, the forecast profiles will approach a linear path with certain growth rate. The transitory component will have no effect on the conditional forecast at the indefinite future. The permanent component of a series is the
The permanent component $\log K_P^t$ follows

$$\log K_{t+1}^P - \log K_t^P = \log \gamma_t + \hat{\gamma}_t$$  \hspace{1cm} (35)$$

and the cyclical component\(^{27}\) is

$$\log K_{t+1}^c = \log G_t^c$$

$$= w_1^k \log K_{t-1}^c + w_3^k \hat{\gamma}_t + e_t^k$$

Now we move on to BN decomposition of the wage process. Differentiating the perceived law of motion for wages yields

$$\Delta \log w_t = w_1^w \Delta \log k_t + w_3^w \Delta \hat{\gamma}_t + \Delta e_t^k$$

Combining (34), (26) and (32) yields

$$\Delta \log W_t = \Delta \log w_t + \Delta \log X_t$$

$$= w_1^w \Delta \log k_t + w_3^w \Delta \hat{\gamma}_t + \Delta e_t^k + \log \gamma + \hat{\gamma}_t$$

$$= w_1^w \frac{(1 - L) (w_3^k \hat{\gamma}_{t-1} + e_{t-1}^k)}{1 - w_1^k L} + w_3^w \Delta \hat{\gamma}_t + \Delta e_t^k + \log \gamma + \hat{\gamma}_t$$

The permanent component becomes

$$\log W_t^P - \log W_{t-1}^P = \log \gamma + \hat{\gamma}_t$$  \hspace{1cm} (36)$$

\(^{27}\)The definition of the cyclical component is negative of the one used in Beveridge and Nelson (1981).
and the cyclical component $\log W^c_t$ is

$$\log W^c_t = w^k_t \log W^c_{t-1} + w^w_3 \hat{\gamma}_t + (w^w_1 w^k_3 - w^k_1 w^w_3) \hat{\gamma}_{t-1} + e^k_t$$

The permanent and cyclical component of the rental rates process are

$$(\log R^K_t)^P - (\log R^K_{t-1})^P = 0 \quad (37)$$

$$(\log R^K_t)^c = w^k_t (\log R^K_{t-1})^c + w^w_3 \hat{\gamma}_t + (w^w_1 w^k_3 - w^k_1 w^w_3) \hat{\gamma}_{t-1} + e^r_t$$

We now consider an alternative PLM where agents’ subjective beliefs are specified in detrended and log-linearized variables but not percentage deviations from the steady state as in Bullard and Duffy (2005) or Mitra, Evans and Honkapohja (2013). In our context, instead of the PLM (23)-(25), suppose agents perceive

$$R^K_t = \omega^r_t + \omega^k_t k_t + \omega^\gamma_t \hat{\gamma}_t + e^r_t \quad (38)$$

$$w_t = \omega^w_t + \omega^w_t k_t + \omega^\gamma_t \hat{\gamma}_t + e^w_t \quad (39)$$

$$k_{t+1} = \omega^k_t + \omega^k_t k_t + \omega^\gamma_t \hat{\gamma}_t + e^k_t \quad (40)$$

Note the rental rates, wage rates, capital, productivity shocks are detrended and linearized.
but not percentage deviations. The above three equations can be reformulated as

\begin{align*}
\hat{R}_t^K &= \tilde{\omega}_0^r + \omega_1^r \hat{k}_t + \omega_3^r \hat{\gamma}_t + e_t^r 
\hat{w}_t &= \tilde{\omega}_0^w + \omega_1^w \hat{k}_t + \omega_3^w \hat{\gamma}_t + e_t^w 
\hat{k}_{t+1} &= \tilde{\omega}_0^k + \omega_1^k \hat{k}_t + \omega_3^k \hat{\gamma}_t + e_t^k
\end{align*}

(41) (42) (43)

where \( \tilde{\omega}_0^r = \omega_0^r + \log R_K + \omega_1^r \log k + \omega_3^r \log \gamma \), \( \tilde{\omega}_0^w = \omega_0^w + \log w + \omega_1^w \log k + \omega_3^w \log \gamma \), and \( \tilde{\omega}_0^k = \omega_0^k + \omega_1^k \log k + \omega_3^k \log \gamma \) are constant terms and do not matter for agents’ perceived trend growth. The belief specification (38)-(40) still implies that agents’ perceived law of motion for the trend is (35), (36) and (37) because the proof for the PLMs (23)-(25) can continue to be used for (41)-(43).

**F Graphic Illustration of Our Learning Model**

We illustrate how our learning model (described in Section 4 of the paper) is conceptually different from the formulation of learning with detrended data and with the full-information RE benchmark. Figure A.3 illustrates agents’ knowledge of the trend component of non-stationary variables (e.g., income, output, capital) in these models by considering a one-off, positive shock to labor productivity in period 1. The lower solid line is the Balanced Growth Path (BGP) before the shock. Under RE, agents know that the shock shifts the trend growth path upward and that it is mapped one-to-one to the impact increase of the level of the trend. In addition, agents know that the slope of the new BGP (i.e., the middle solid line) is identical to that of the old path.
In the learning model where agents learn the law of motion for detrended variables, agents too have exact knowledge that the shock is mapped one-to-one to the shift of the new trend path and that the slope of the new BGP is not changed (as under RE). Unlike RE, however, in this learning model agents do not know the location of the two BGPs and are uncertain about the level of the trend component.

In our learning model, agents do not have exact knowledge of the new BGP relative to the old one. They are uncertain about both the level and slope of the BGP after the shock. The dotted solid line at the top in Figure A.3 represents the agents’ perceived path for the trend after the shock in our learning model. As agents do statistical filtering, adding a new observation to agents’ information set changes the estimate of both the level and slope. Thereafter, agents gradually revise their beliefs of the level and trend growth over time. To reiterate, under RE or in models with learning detrending variables, agents know that the long-run growth rates of non-stationary variables are identical to each other. In our model agents can temporarily have the belief that the long-run growth rates of different variables are not equal.

</table>

Panel A: Autocorrelation of gaps for long-run growth or errors for short-term forecasts

\[Y^{TG}\] 0.99 0.99 0.99 0.99 0.99

\[(Y/H)^{TG}\] 0.995 0.99 0.99 0.99 0.99

\(\rho^Y\) 0.51 0.48 0.48 0.47 0.45

\(\rho^{RK}\) 0.51 0.48 0.48 0.47 0.46

Panel B: Correlation between long-run output growth forecasts and HP-filtered data

Output 0.40 0.42 0.47 0.48 0.49

Consumption 0.37 0.39 0.44 0.45 0.47

Investment 0.41 0.43 0.47 0.48 0.49

Hours 0.42 0.43 0.47 0.48 0.49

Panel C: Correlation between long-run Y/H growth forecasts and HP-filtered data

Output 0.40 0.42 0.45 0.47 0.48

Consumption 0.37 0.39 0.43 0.44 0.46

Investment 0.41 0.42 0.47 0.47 0.48

Hours 0.41 0.43 0.45 0.47 0.47

Panel D: Business cycle statistics

Amplification

\(\sigma_{Y\_dif}\) 40\% 40\% 47\% 49\% 52\%

\(\sigma_1/\sigma_{Y\_dif}\) 2.48\% 2.48\% 2.61\% 2.64\% 2.68\%

\(\sigma_H/\sigma_{Y\_dif}\) 0.51\% 0.75\% 0.81\% 0.83\% 0.85\%

Propagation 0.51 0.48 0.48 0.47 0.45
Note: \( Y^{TG} / (Y/H)^{TG} \) stand for the autocorrelation of gaps between forecasts of long-run output growth (output per hour growth) and HP-filtered output growth (output per hour growth). \( \rho^{RK} \) and \( \rho^Y \) stand for the autocorrelation of one-period ahead forecast errors in rental rates and output growth, respectively.
Table A.7: Learning model with alternative labor supply elasticities: statistics

| Autocorrelation of gaps for long-run growth or errors for short-term forecasts | Correlations |
|---|---|---|---|---|
| $(Y/H)^{TG}$ | $\rho^R$ | $\rho^Y$ | $\rho^C$ | $\rho^I$ | $\rho^H$ |
| **Data** | 0.96 | 0.96 | 0.38 | 0.37 | 0.47 | 0.69 | 0.46 | 0.30 |
| **Baseline Learning** | 0.99 | 0.99 | 0.48 | 0.48 | 0.47 | 0.44 | 0.47 | 0.47 |
| **Learning: $\epsilon^{-1}_H = 7$** | 0.99 | 0.99 | 0.43 | 0.44 | 0.45 | 0.42 | 0.46 | 0.46 |
| **Learning: $\epsilon^{-1}_H = 2$** | 0.99 | 0.99 | 0.27 | 0.27 | 0.41 | 0.35 | 0.41 | 0.41 |

| Business cycle statistics |
|---|---|---|---|---|---|---|
| $\sigma_Y$ | $\sigma_C/\sigma_Y$ | $\sigma_I/\sigma_Y$ | $\sigma_H/\sigma_Y$ | $\Delta_C$ | $\Delta_Y$ | $\Delta_I$ |
| **Data** | 1.51 | 0.55 | 2.88 | 0.92 | 0.27 | 0.30 | 0.35 |
| **Baseline RE** | 0.80 | 0.75 | 1.74 | 0.37 | -0.00 | -0.01 | -0.01 |
| **Baseline Learning** | 1.51 | 0.47 | 2.61 | 0.81 | 0.24 | 0.48 | 0.37 |
| **RE: $\epsilon^{-1}_H = 7$** | 0.77 | 0.75 | 1.73 | 0.34 | -0.00 | -0.01 | -0.01 |
| **Learning: $\epsilon^{-1}_H = 7$** | 1.34 | 0.48 | 2.59 | 0.76 | 0.16 | 0.44 | 0.31 |
| **RE: $\epsilon^{-1}_H = 2$** | 0.67 | 0.77 | 1.67 | 0.21 | -0.00 | -0.01 | -0.01 |
| **Learning: $\epsilon^{-1}_H = 2$** | 0.87 | 0.53 | 2.52 | 0.49 | -0.19 | 0.28 | 0.11 |

Note: The top right panel reports the correlation between long-run output growth forecasts and cyclical activity. $\Delta_C$, $\Delta_Y$, $\Delta_I$ are autocorrelations of consumption, output and investment growth.
