Key words
Heart failure, heart failure with preserved ejection fraction, endothelial progenitor cells, microparticles
Heart failure (HF) with preserved ejection fraction (HFpEF) has emerged as a major problem of modern cardiology. In contrast to HF with systolic impairment advances in management of HFpEF have been humble and there is lack of proven effective treatment to improve longevity and reduce disability in such patients. Futility of the medications established in systolic HF to help subjects with HFpEF reflects difference in the pathophysiological mechanisms of the two forms of HF. Good understanding of these mechanisms is essential for discovery of new treatments in the future.

The numbers of endothelial progenitor cells (EPCs) are upregulated in systolic HF and their numbers correlate with levels of various cytokines, such as tumor necrosis factor-alpha. However EPCs counts vary depending on the stage of HF with relatively higher levels seen in mild or well-controlled disease but the numbers decrease progressively in advanced HF stages.

Hypertension is a major cause of HFpEF as opposed to ischemia in systolic HF. Diastolic dysfunction and abnormal cardiac stiffness are recognized factors predisposing to the development of HFpEF in patients with high blood pressure. Hypertension is related to impairment of EPC migratory capacity in vitro. This may be partly explained by upregulation of angiotensin II, a molecule shown to reduce telomerase activity in EPCs and to accelerate their senescence.

Circulating microparticles have been appreciated as an important component of intercellular communication. They may be involved in more complex regulatory pathways due to their capacity to deliver multiple molecules in the same lipid envelope and to specifically target particular types of cells using their surface
receptors. Patients with hypertension and systolic HF have abnormal levels of
different types of blood microparticles but data on microparticles in HFP EF are
scarce.

EPCs are diverse and they embrace cells of different progeny.6 Two types of EPCs
appear to be of particular relevance. ‘Late’ EPCs are extremely scarce in circulation
and they most likely represent cells resident within the endothelium. When
appropriately stimulated they have immense proliferative capacity and can give origin
to endothelium cells per se. However, their assessment is limited but the requirement for
long-term in vitro culture experiments. The other major type of EPCs are so called
‘early’ EPCs, which produce numerous endothelial like cells within few days of in
vitro culture. They have been shown to be predominantly of monocytic origin and
they contribute to angiogenesis by releasing appropriate cytokines, chemokines,
growth factors, etc., thus orchestrating mobilization of other cell types and
modulating activity of the tissue resident cells. Given the monocytic origin of these
cells they can be assessed by flow cytometry from fresh blood samples. This
opportunity has been utilized Berezin et al. in their study published in this issue of
EBioMedicine.7

Berezin et al. have demonstrated significant differences in the pattern of circulating
EPCs and endothelial microparticles in patients with HF with reduced or preserved
ejection fraction.7 The study provides several interesting observations. Among the
different EPC phenotypes assessed, only CD14+ cells (i.e., cells of monocytic origin)
were independently associated with HFP EF. This accords with extensive and ongoing
cardiac remodeling in patients with HFP EF.
However detailed relationship between the tested parameters and measures of cardiac remodeling and outcomes were beyond the scope of the present study and need to be established in the future in prospective trials. Such information is essential to establish whether the tested pathways could produce clinically relevant therapeutic targets.

Of interest, in the study by Berezin et al. HFpEF was related to upregulation of monocytes with angiogenic phenotypy rather than cells with ‘classical’ CD34+CD309+ EPC phenotype. This fits well in the progressively better-understood role of a specific monocyte population (i.e., ‘intermediate’ or Mon2 subset) in pathogenesis and prognostication in several cardiac disorders including HF. In fact, this subset has been shown to have highest of all monocytes expression of CD309, Tie-2 and a range of other receptors involved in angiogenesis and tissue remodeling. The results obtained by Berezin et al also correspond to recent observations that non-monocytic circulating EPCs can in fact be downregulated in HFpEF compared to controls without HF thus highlighting the importance of careful characterization of specific phenotype of cells assessed under generic term of EPCs.

Berezin et al. show that changes in proportions of certain types of microparticles (CD31+ could be shed from both endothelial cells and platelets) and angiogenic monocytes are linked to the type of HF. It is possible that these changes are secondary to the degree of the background ischemia or shifts in cardiac and vascular hemodynamics associated with particular HF form (for example, increased endothelial shear stress in hypertension). However it can also reflect poorly understood aspects of endothelial dysfunction. Indeed, whilst the role of endothelial
dysfunction is well-established magnitude and nature of endothelial changes in HFpEF is less clear.

Extensive experimental work is also warranted to identify and describe the whole length of the pathophysiological pathways implicated in the processes mediated by angiogenic monocytes and microparticles. This will help to determine the key components of the pathways, which will help to modulate them in the desired direction.

The study does not answer the question of whether the observed upregulation of biomarkers is involved in the development of HFpEF or they reflect a mechanism aiming to contrabalance the pathogenic factors or to promote adaptation of the cardiovascular system to hemodynamic changes. These questions will need to be answered in the future. Overall the study by Berezin and colleagues provides new insight in processes differentiating HFpEF and systolic HF and it leads to a string of interesting hypotheses to be tested in the future.
