Abstract

The last quarter of a century has seen a dramatic rise of interest in the spatial constraints on multisensory integration. However, until very recently, the majority of this research has investigated integration in the space directly in front of the observer. The space around us, however, extends in three spatial dimensions in the front and to the rear beyond such a limited area. The question to be addressed in this review concerns whether multisensory integration operates according to the same rules throughout the whole of 3-D space. The results reviewed here not only show that the space around us seems to be divided into distinct functional regions, but they also suggest that multisensory interactions are modulated by the region of space in which stimuli happen to be presented. We highlight a number of key limitations with previous research in this area, including: 1) The focus on only a very narrow region of 2-D space in front of the observer; 2) The use of mostly static stimuli; 3) The study of observers who themselves have been mostly static; and 4) The study of isolated observers. All of these factors may change the way in which the senses interact at any given distance, as can the emotional state/personality of the observer. In summarizing these salient issues, we hope to encourage researchers to consider these factors in their own research in order to gain a better understanding of the spatial constraints on multisensory integration as they affect us in our everyday life.

Keywords: multisensory, crossmodal, spatial, depth, distance, attention, peripersonal.
Introduction

The field of multisensory research has grown steadily over the past decade or so (see Bremner, Lewkowicz, & Spence, 2012; Murray et al., 2013; Spence & Driver, 2004; Stein, 2012; Stein et al., 2010; Van der Stoep, Nijboer, Van der Stichel, & Spence, 2015, for reviews). Advances in our understanding of how the brain processes multisensory information have been made by means of neurophysiological, psychophysical, neuropsychological, neuroimaging, and computational modeling studies of multisensory interactions. Whereas visual, auditory, and tactile information are initially processed independently, they are integrated at various stages of sensory information processing (Calvert & Thesen, 2004\(^1\)). The conditions under which multisensory interactions occur, and the behavioral benefits (or costs) that accrue as a result of multisensory integration, are now starting to become clearer. So, for example, it is now evident that information from the different senses is integrated over a range of spatial and temporal separations (Meredith & Stein, 1983; Vroomen & Keetels, 2010; though see also Spence, 2013). Furthermore, the circumstances under which attention and multisensory integration interact are now also being more clearly elucidated (see Koelewijn, Bronkhorst, & Theeuwes, 2010; Talsma, 2015; Talsma, Senkowski, Soto-Faraco, & Woldorff, 2010, for reviews). Multisensory integration can, for instance, occur before attentional selection (e.g., Bertelson, Vroomen, De Gelder, & Driver, 2000; Soto-Faraco, Navarra, & Alsius, 2004; Spence & Driver, 2000; Vroomen, Bertelson, & De Gelder, 2001), is modulated by exogenous and endogenous spatial attention (either enhancing or decreasing multisensory integration; e.g., Van der Stoep, Van der Stigchel, & Nijboer, 2015; Talsma & Woldorff, 2005; Zou, Müller, & Shi, 2012), and attending more to one sense than to the others has also been shown to modulate multisensory
\(^1\)We will not discuss the chemical senses in this review. See Spence (2015) for more on multisensory flavour perception.
integration (e.g., Alsius, Navarra, Campbell, & Soto-Faraco, 2005; Mozolic, Hugenschmidt, Peiffer, & Laurienti, 2008; Talsma, Doty, & Woldorff, 2007).

As yet, however, one attribute of multisensory signals that has received relatively less attention from the research community is the distance from which information is presented (with the exception of distance-related changes in multisensory temporal perception; e.g., Alais & Carlile, 2005; Arnold, Johnston, & Nishida, 2005; Engel, & Dougherty, 1971; Harris, Harrar, Jaekl, & Kopinska, 2009; Sugita & Suzuki, 2003; see also below). It is striking that this should be the case because we obviously perceive multisensory information from various distances on a daily basis.

The mere fact that our sense of touch, vision, and audition differ in the distance at which they are able to register information suggests that their interactions may also be distance-dependent. We are able to perceive visual information from a great distance but selectively in frontal space. Audition allows us to perceive sounds from various distances from all directions. In contrast, our sense of touch allows us to perceive stimulation only when energy reaches the skin. That is, usually only from events happening at close proximity (an exception may be our ability to perceive heat, even from far away sources like the sun). Bodily movements and handheld tools can extend the range in which we can employ touch to sense the world, but, even with such extended reach, the maximum distance is still rather limited if compared to audition and vision. The different spatial ranges at which events can stimulate our various sensory systems imply that the way in which the senses interact could depend on the distance from which such events are perceived.

Various studies have demonstrated a distance-dependent modulation of multisensory interactions, which suggests that source distance is indeed a factor worthy of consideration in multisensory research (e.g., Canzoneri, Magosso, & Serino, 2012; Farnè & Làdavas, 2002;
In this review, we provide an overview of some of the most important factors that need to be taken into account when investigating multisensory interactions. Our goal in writing this review is to underline that it is crucial to be aware of the fact that multisensory interactions are dependent on the region of space in which one presents one’s stimuli. Therefore, our hope is that we may be able to stimulate researchers to more carefully consider the distance or depth from which information is presented when investigating multisensory interactions.

First, we discuss the basis on which the space around the human body has been divided into distinct regions (see Figure 1). A distinction can be made here between different regions of space based on: (1) The strength of multisensory interactions; (2) The different functions associated with each region (e.g., grasping, communicating, navigation); and (3) An impaired ability to process or integrate information that is presented within a certain region of space as shown by neuropsychological studies of brain-damaged patients (e.g., Bisiach, Perani, Vallar, & Berti, 1986; Halligan & Marshall, 1991; Làdavas & Farnè, 2004; Vuilleumier, Valenza, Mayer, Reverdin, & Landis, 1998; see Occelli, Spence, & Zampini, 2011; Previc, 1998; Van der Stoep, Nijboer, van der Stigchel, & Spence, 2015, for reviews).

Furthermore, we highlight the fact that the research that has been conducted to date has been very limited in terms of the regions of space in which multisensory stimuli have been
presented, and hence multisensory interactions have been investigated. Not only have the majority of studies presented the stimuli in a relatively small region of frontal space, more distal and lateral locations have been largely ignored (see Figure 2). Additionally, studies of multisensory interactions in rear space and those studies in which stimuli have been presented at different elevations are surprisingly scarce as well.

[Insert Figure 2 about here]

Multisensory interactions have primarily been studied in those situations in which not only the observer, but also the stimuli, remained static (though some researchers have been investigating multisensory integration using looming and receding stimuli, e.g., Canzoneri, Magosso, & Serino, 2012; Cappe, Thelen, Romei, Thut, & Murray, 2012; Cappe, Thut, Romei, & Murray, 2009; Cléry et al., 2015). In everyday life, however, both the observer and the surrounding stimuli often move. This necessitates a neural system that is capable of keeping track of multisensory stimuli and rapidly and continuously updating the representation of the body in space, given that the movement of the observer’s body can change the distance from the stimuli.\[2\]

Distance-dependent modulations of multisensory interactions may, in addition, be further affected by social factors, such as the sheer presence of, trust in, or cooperation with, other individuals or anxiety related to the presence of certain stimuli (Brozzoli, Ehrsson, & Farnè, 2014; de Vignemont & Iannetti, 2015; Ferri, Tajadura-Jiménez, Väljamäe, Vastano, &

\[2\] There may be an important role for crossmodal spatial remapping and integration with body posture here (Spence & Driver, 2004).

Last, but by no means least, we will discuss how all these modulations might be explained in the context of the predictive coding framework.

**Dividing space**

The idea that distinct regions of space relative to the body are represented differently by the brain might at first sound odd, given that we generally perceive the space around us as continuous. Yet support for this notion comes from several social psychological, psychophysiological, neurophysiological and neuropsychological studies of (multisensory) spatial perception. The notion that the brain might process stimuli in different regions of space differently has emerged from neurophysiological studies of a particular kind of multisensory neuron. Several authors have observed that certain bimodal neurons in frontal and parietal areas of the macaque monkey have visual spatial RFs aligned with tactile RFs extending a certain limited distance from the body (e.g., Duhamel, Bremmer, BenHamed, & Graf, 1997; Graziano & Gross, 1994; Graziano, Hu, & Gross, 1997; Rizzolatti, Fadiga, Fogassi, & Gallese, 1997; Rizzolatti, Scandolara, Matelli, & Gentilucci, 1981).

The visual and tactile RFs of many of those bimodal neurons remained spatially aligned, even after the movement of a limb, such as a hand or arm. This indicates that the position of a body part in space is updated in order to enable relevant multisensory interactions in terms of the spatial layout of events in the environment relative to the body. The depth from which stimuli are presented is, however, not only important when it comes to visuotactile
integration, but also for audiotactile integration (Graziano, Reiss, & Gross, 1999). In particular, bimodal and trimodal neurons in the ventral premotor cortex of the macaque monkey have been shown to be sensitive to sounds presented approximately 10 cm from the head of the animal, but not to the same sounds when presented at a distance of 30 or 50 cm. This spatial region of space has been termed peripersonal space (PPS; of the hand and of the head in these examples; see Cardinali, Brozzoli, & Farnè, 2010 for a discussion of the distinction between PPS and reachable space). Similar observations have been made in both neurotypical, and brain-damaged humans, in both frontal and rear space (e.g., Farnè & Ládavas, 2002; see Occelli, Spence, & Zampini, 2011, for a review). These results can therefore be taken to show that the distinction between peri- and extrapersonal space is not only true for frontal space, but also for rear space.

Several neuropsychological studies of visuospatial neglect have demonstrated that following stroke, neglect may well be distance-specific (e.g., Halligan & Marshall, 1991). That is, neglect may occur selectively in either peripersonal or extrapersonal space, or in both regions of space (Aimola, Schindler, Simone, & Venneri, 2012; Bisiach et al., 1986; Cowey, Small, & Ellis, 1994; Halligan & Marshall, 1991; Van der Stoep et al., 2013; Vuilleumier et al., 1998). Such results indicate that a distinction between peripersonal and extrapersonal space can be observed in terms of deficits in visuospatial attention. Depending on the location of the brain lesion, visuospatial attention would seem to be impaired in either peripersonal (dorsal lesions) or extrapersonal space (ventral lesions). There are some indications that damage to brain structures that are connected to both the dorsal and ventral visual processing streams can give rise to neglect in both regions of space (middle temporal cortex, frontal cortex, anterior cingulate cortex, see Aimola et al., 2012).

Furthermore, it has been suggested that different combinations of sensory information might be more or less relevant depending on the distance from which this information happens to be
presented (Previc, 1998; Van der Stoep, Nijboer, Van der Stigchel, & Spence, 2015). For example, touch and vision are dominant in peripersonal space, as they may imply an interaction between the body and the environment (e.g., for grasping or defense), whereas auditory and visual information may be more relevant in extrapersonal space as they provide useful information about farther objects, for spatial orienting, navigation and interaction with others (e.g. during conversation). Space can thus also be divided based on the functions linked to different regions of space, and accordingly to the dominant senses that are associated with those functions.

**Limited focus of previous research**

Research concerning the way in which multisensory interactions are modulated by the distance between the stimuli and the observer has mainly focused on those interactions taking place in *frontal peripersonal* space. Yet in order to gain a better understanding of how the senses interact in everyday life, it is important to understand how multisensory interactions change as a function of the position of the source of multisensory stimulation in full three-dimensional (3-D) space. Figure 2 (left panel) provides an overview of the distances at which stimuli have been presented in a sample of previous studies of multisensory interactions in different depth-planes (see Appendix A for details, see Appendix B for a similar figure including studies of temporal perception using distances up to 50 m). What becomes clear when one looks at Figure 2 (left panel and Appendix B) is that studies on multisensory
interactions in rear space, lateral space, and distances out of reach are underrepresented relative to studies of multisensory interactions in peripersonal and reachable space.\(^3\)

Based on the studies that are available, however, it has, in recent years, become increasingly apparent that the way in which sensory information interacts changes as a function of the distance from which that information is presented from the observer. What is perhaps even more striking is that the elevation of stimuli with respect to the observer has almost never been manipulated (see Figure 2, right panel). The particular spatial alignment of multisensory stimuli in terms of elevation also affects how the sense interact given that there are, for example, differences in the reliability of determining the elevation of auditory and visual information (e.g., Corneil, Van Wanrooij, Munoz, & Van Opstal, 2002; Frens, Van Opstal, & Van der Willigen, 1995; Ten Brink, Nijboer, Van der Stoep, & Van der Stigchel, 2014).

In addition, several studies have indicated that multisensory interactions are different for multisensory stimuli that are presented in the peripheral as compared to the central visual field. For example, the double-flash illusion is much stronger when sound and light are presented in the periphery as compared to when they are presented at the fovea (Shams, Kamitani, & Shimojo, 2000; Shams, Kamitani, Thompson, & Shimojo, 2001). Furthermore, audiovisual temporal binding windows tend to be larger for those stimuli presented out in the periphery (Stevenson, Fister, Barnett, Nidiffer, & Wallace, 2012). Interestingly, in line with these findings, it has been observed that the density of direct projections between auditory and visual cortex is larger in the peripheral than in the central visual field, at least in monkeys (Falchier, Clavagnier, Barone, & Kennedy, 2002).

\(^3\) This becomes all the more clear when one thinks of all the studies of multisensory integration in which depth was of no particular interest. In such studies, stimuli are often presented at a fixed distance in frontal space (~60-80 cm from the body).
Studying multisensory interactions in different regions of 3-D space (i.e., changing the position of stimuli in the front-back, left-right, and up-down dimensions) may therefore be expected to provide a window into how multisensory perception changes in those situations that are more representative of everyday life.

**Visuo-tactile and audio-tactile interactions and the concept of peripersonal space**

Those multisensory interactions that are relevant to the body (i.e., multisensory stimulation involving the sense of touch) seem to be especially pronounced in the PPS around different body parts. Various studies have shown that responses to tactile stimulation on the hand, face or trunk are faster when a sound is presented close to the stimulated body-part relative to those situations in which sound is presented in far space (e.g., Canzoneri, Magosso, & Serino, 2012; Canzoneri, Ubaldi, Rastelli, Finisguerra, Bassolino, & Serino, 2013; Farnè, & Làdavas, 2000; Galli et al., 2015; Noel et al., 2014; Noel, Blanke, & Serino, in press; Teneggi, Canzoneri, Di Pellegrino, & Serino, 2013). These findings are in line with observations of visual, auditory, and tactile RFs of multisensory neurons that respond to sensory stimuli that are presented within a limited spatial range from the body (see Graziano & Cooke, 2006, for a review). The size of these spatial RFs essentially determines the size of the PPS around different body parts.

Neurophysiology studies have identified neuronal populations with multisensory receptive fields covering the space around the hand, face and trunk, within a network of fronto-parietal areas spanning from the ventral premotor cortex (Fogassi et al., 1996, Graziano et al., 1997), the ventral intraparietal area (Avillac et al., 2005; Duhamel et al., 1997,) and parietal area 7 (Hyvarinen, 1981; Leinonen, 1980; see Graziano & Gross, 1994, and Cléry, Guipponi, Wardak, & Hamed, 2015, for reviews). Human neuroimaging studies have further confirmed...
that homologous premotor and parietal areas preferentially respond to, and integrate, those
stimuli that are presented on, or close to, the hand (Brozzoli et al., 2011; Makin et al., 2007),
face (Bremmer et al., 2001, Sereno & Huang, 2006) or trunk (Huang et al., 2012).

Different body-part centered PPS representations might serve different functional roles. The
peri-hand space may be mainly involved in hand-object interactions that can be appetitive or
defensive in nature: It is mainly represented by premotor and parietal areas, which not only
integrate multisensory stimuli around the hand, but also project to the motor system in order
to trigger the appropriate responses (Avenanti et al., 2012; Cooke et al., 2003, 2004; Makin et
al., 2009; Serino et al., 2009). The peri-hand space also dynamically updates its size/shape as
a function of changes in upper limb function or structure, such as after tool-use (Canzoneri et
al., 2013; Farnè & Lèdavas, 2000; Maravita et al., 2001; see Maravita & Iriki, 2004, for a
review, and Serino et al. 2015 for a computational account of these effects), amputation and
prosthetic implementation (Canzoneri, Marzolla, Amoresano, Verni, & Serino, 2013), and
immobilization (Bassolino et al., 2015).

The peri-face space is likely to be more involved in social interactions, as its boundaries are
sensitive to the presence of, and interaction with, other people (e.g., Tennegi, Canzoneri, di
Pellegrino, & Serino, 2013) and varies depending on individual personality traits, such as
anxiety (Sambo & Iannetti, 2013; see also below). Finally, the peri-trunk space may serve as
a global representation of the whole-body in space, as it includes the other body-part centered
PPSs, shapes during whole body movements (e.g., walking, Noel et al., 2014) and is centered
at the perceived location of the self in space (Noel et al., 2015). Thus, there would seem to be
a series of body-part centered PPS representations, underlying rather specific sensory-motor
or cognitive functions, and a whole-body representation of PPS, representing a primary
interface between the bodily self and the environment.
The dynamic observer

In many of the studies of multisensory interactions in peripersonal space that have been conducted to date, the observer has been static (that is, they have had to sit passively on a chair or else, on occasion, they have had to stand still). As such, the presentation of dynamic multisensory stimuli may provide information on the updating of multisensory interactions when objects approach the static observer or during passive movement through the environment (e.g., as when driving; see Moeller, Zoppke, & Frings, 2015 for the effects of driving on distance estimation). However, when humans are actively moving through the environment (e.g., while walking) or when interacting with it (e.g., during grasping), the position of the body or a body-part in space will change constantly relative to the stimuli in the environment. Therefore, the representations of peripersonal and extrapersonal space will obviously need to be updated in order to maintain functional, enable effective interaction with the environment, and to maintain a proper margin of safety around the body in order to maintain body integrity (see e.g., Graziano & Cooke, 2006; de Vignemont & Iannetti, 2014). Recent findings support the view that the multisensory interactions in space vary depending not only as a consequence of object moving around the observer, but also depending on the movements of the observer in the environment. We will first review evidence supporting this claim in the case of hand-objects interaction, and then with respect to movement of the body as a whole.

Multisensory interactions during goal oriented actions
Despite the above recalled increase of interest in multisensory perception during the last few decades, virtually nothing is yet known about whether and how information from the different senses interacts when the brain starts transforming the intention to act into a motor program. This gap in our knowledge is even more surprising when it is considered that several studies have demonstrated the involvement of PPS in the guidance of involuntary, defensive movements. In the monkey, electrical stimulation of multisensory areas may evoke rather complex patterns of hand, arm, and head movements such as the withdrawal of the hand, the turning of the head, or the lifting the hand as if to defend the head, which are largely compatible with defensive reactions (e.g., Graziano et al. 2002). It has been suggested that such adaptive responses, possibly evoked by multisensory neurons, are fast and mainly occur outside of the control of top–down voluntary mechanisms.

In line with this prediction, electrophysiological investigations in humans have indeed revealed that the motor cortex is very quickly ‘informed’ when an object appears in the visual field and happens to be approaching one’s hand. As compared to a condition were the object was also falling, but its landing position was far removed from the location of the participant’s hand, hand-approaching objects were able to modify the corticospinal excitability of the visually ‘threatened’ hand within just 70 milliseconds of its appearance (Makin et al., 2009; see also Serino et al., 2009). Importantly, such an automatic hand-centered coding of visual PPS was selective for approaching balls, as static visual distractors did not modulate activity in the motor cortex. Even more important, control conditions for both overt and covert orienting of spatial attention ruled out any major role played by the latter in the hand-centred coding of PPS, a finding that fits well the need for a defensive system to be efficient enough even in unattended conditions (Makin et al., 2009, 2012).

For such a sensorimotor defensive system to be really effective, not only should general information about whether an object is approaching the hand be processed rapidly, but also
the more specific information about which hand is approached. This hypothesis was recently
tested by probing motor cortex excitability (Makin, Brozzoli, Cardinali, Holmes, & Farnè, 2015). The participants’ right hand was concealed while a falling red ball rapidly approached either left- or right-handed dummy hands that were located either in an orientation that was either plausible (egocentric perspective) or implausible (allocentric perspective). It was found that within a very short time-window (i.e., 70ms from the appearance of the ball in the visual field), the human motor system is already capable of coding not only the proximity of an object to a hand (near vs. far), but also which hand this object potentially threatens. When the ball approached an egocentrically oriented dummy hand, motor evoked potentials were significantly reduced for an anatomically congruent (right) dummy hand, as compared with an incongruent (left) dummy hand. These findings are in line with the neurophysiological evidence gathered in the monkey showing that the tonic activity of certain multisensory neurons is modulated by hand identity. That is, by whether a left or right hand is visually presented in an egocentric perspective (Graziano, Cooke, & Taylor, 2000). These findings therefore provide support for the general claim that PPS coding may well serve to perform defensive actions.

These multisensory interfaces might be adaptive not only for defensive, but also for appetitive actions, such as grasping a glass of water (e.g., Gardner et al., 2007; Marzocchi, Breveglieri, Galletti, & Fattori, 2008). In this respect, the properties of multisensory neurons that we have recalled previously may allow the brain to represent a target object in a coordinate system centred on the body (e.g., the hand) that, in addition, could be continuously updated during bodily movements. It is worth noting here that some bimodal neurons have been documented that respond when the arm is voluntarily moved within the reaching space of the animal and have been proposed to code goal-directed actions. This question was addressed in a study in neurotypical humans by having participants perform a modified
version of the classical Crossmodal Congruency Effect (CCE) paradigm (see Spence, Pavani, Maravita, & Holmes, 2004, 2008, for reviews). By taking the changes in the magnitude of the CCE as a proxy for changes in PPS, Brozzoli and colleagues (Brozzoli et al, 2009), were able to provide support for the hypothesis that voluntarily acting on objects triggers a hand-centred remapping of multisensory perception (see Brozzoli, Makin, Cardinali, Holmes, & Farnè, 2012, for a review). The authors asked healthy participants to discriminate touches on the hand they used to grasp an object that contained task-irrelevant visual distractors. In this case, crossmodal stimulation was applied to either the grasping or the non-grasping hand. There was no cue-target delay between tactile targets and visual distractors thus enhancing the likelihood of causing multisensory integration instead of crossmodal spatial attention (McDonald, Teder-Sälejärvi, & Ward, 2001; Van der Stoep, Spence, Nijboer, & Van der Stigchel, 2015). This visuo-tactile task provided a measure of how (much) the visual-tactile interaction varied, in real time, during the execution of the action. When compared to a static condition prior to movement initiation, the start of the grasping action selectively increased the interference exerted by visual inputs originating from the (far) target object on tactile stimuli delivered to the grasping hand. In addition, a further increase in the magnitude of the CCE was observed shortly after (250ms) the onset of the hand movement. That is, when the hand had initiated its travelling path towards the target object, yet was still far away from it. The increase in CCE was observed both at the start of the movement and during the subsequent unfolding of the action. This not only indicates that PPS can be remapped as a function of the execution of voluntary actions, but also demonstrates that remapping occurs in an on-line fashion.

Such a dynamic, action-dependent modulation of PPS, which - by the way - also reveals that PPS remapping can occur independent of tool-use (see also Serino, Canzoneri, Marzolla, di Pellegrino, & Magosso, 2015), was further illustrated by a follow-up study in which different
types of actions were performed. Brozzoli and his colleagues assessed the effects of performing different actions towards the same object on the on-line modulations of PPS, as measured by the same variant of the CCE paradigm (Brozzoli, Cardinali, Pavani, & Farnè, 2010). Neurotypical participants had to either grasp or point towards an object while discriminating whether tactile stimuli were delivered on their right index finger or thumb and ignoring visual distractors (from the target object). The strength of visuo-tactile interaction was probed before the movement, as well as at action onset and during action execution. When compared to the static condition, the grasping and the pointing actions had similar effects of increasing the CCE at the action onset (prior to the movement). That is, when these actions were indistinguishable from the point of view of their kinematics. However, the CCE further increased for the grasping action, but not the pointing one, during the execution phase, when the kinematics of these movements started to diverge. These findings therefore suggest that performing voluntary actions induce a continuous remapping of PPS as a function of the on-line contextual demands imposed by their kinematics (Brozzoli, Cardinali, Pavani, & Farnè, 2010). Preliminary unpublished data from the same laboratory suggested that multisensory interactions may actually occur prior to movement onset and may even be sensitive to the hierarchical structures of complex, multistep movements.

Overall, these findings suggest that performing both defensive and appetitive actions towards objects entails a multisensory link between signals from the environment and the body that is functionally related to the action goal. Recently, researchers investigated whether visuo-tactile interactions are also modulated by the proximity of the hand to an obstacle during a reach-to-grasp movement to a target object (Menger, Van der Stigchel, & Dijkerman, in preparation).

This is an especially interesting question as the obstacle is not the goal of the movement, but it can nevertheless still have a tactile consequence that we often want to avoid (e.g., accidently knocking over your own, or worse still, someone else’s, glass of beer; see De...
Haan, Van der Stigchel, Nijnens, & Dijkerman, 2014). The participants had to grasp a target object in front of them and avoid touching another object that was placed along the trajectory on the outside of the reaching arm. At different positions of the hand along the reaching trajectory, a visual stimulus on the obstacle was simultaneously presented with a tactile stimulus on the hand. The visual and tactile stimuli could either be congruent or incongruent in terms of the side of stimulation. That is, a visual stimulus on the obstacle (on the outside of the arm trajectory) could be simultaneously presented with a tactile stimulus on the index finger (right, congruent with collision) versus on the thumb (opposite side, incongruent with collision). The participants had to respond as rapidly as possible to the onset of the tactile stimulus with their left hand while attempting to grasp a target with their other hand. More specifically, they were required to indicate whether the thumb (left button) or the index finger (right button) was being stimulated. The visuotactile congruency effect increased as the hand that was used to grasp the target (which was also the hand that received tactile stimulation) approached the obstacle. These results could therefore be taken to suggest that representations of peripersonal (hand) space are updated during complex object-oriented actions, depending not only on the goal (object target) of the movement, but also on surrounding potential targets (obstacles).

**Multisensory interactions during whole body movements and while driving**

If multisensory interactions involving tactile stimuli on the body and visual and/or auditory stimuli related to external objects have a functional role in predicting possible contacts between the body and objects in the environment (Graziano & Cooke, 2006; Rizzolatti et al., 1997; Iannetti & de Vignemont, 2015; Clery et al., 2015), then one might expect very different spatial modulations of multisensory interactions when the observer is moving...
through the environment as compared to when he/she is static. Accordingly, Noel et al. (2014) recently reported that the boundary of peripersonal space extends when participants walk as compared to when they were standing still. The boundary of PPS was assessed by measuring the spatial distance at which a sound, looming towards the participant in frontal-space, significantly speeded-up reactions to tactile stimuli on the participant’s body. The experiment was conducted while the participants were either standing or walking on a treadmill, such that the relative distance between the participant’s body and the sound source was equivalent in the two conditions. Nevertheless, while in the static condition sounds occurring closer than ~80-90cm from the participant decreased tactile RTs. This speeding-up of participants’ responses occurred for sounds farther than 2 m in the walking condition, thus suggesting that potential interactions between external stimuli and bodily stimuli are anticipated in the case of a moving perceiver. Compare this case to a situation in which an object is approaching an observer while the observer is moving sideways perpendicular to the approaching object. In this case, when the movement of the observer is taken into account, the object might actually not collide with the body once it gets close, whereas the object would almost certainly hit the observer in a static condition. Predictions concerning multisensory interactions with a stimulus in extrapersonal space may thus be very different depending on whether or not an observer is translating through space, and such effects might be further modulated, depending on whether the observer is passively translated or voluntarily moves.

This issue is directly related to a particular, very interesting case of movements, such as those mediated by vehicles, as, for instance, while driving. The speed of movement during driving is generally much higher when compared to walking. Such high speeds dramatically change the prediction of the distance at which objects start to become relevant in terms of collision with the body. It is currently unknown whether the boundary of peripersonal space extends
even further when we are moving at high speed (either as a driver or a passenger) as compared to when we are walking. Early neurophysiological works on monkeys suggest this might be the case, as Fogassi et al. (1997) reported that the visual RF of peripersonal neurons in ventral premotor cortex extended in space when it was probed with faster as compared to slower looming visual stimuli. However, there may be limits to the amount that peripersonal space can extend in depth (see Holmes, 2012 for a discussion of extension vs. projection of peripersonal space after tool-use). In that case, other factors may also play a role in modulating multisensory interactions between stimuli that are present in different depth-planes. For example, visuospatial attention and estimations about the time-to-contact may be important in determining the outcome of multisensory interactions (see, for example, Kandula, Hofman, & Dijkerman, 2015). The time to contact with an object is obviously dependent on the distance between the object and the body, the speed and direction of movement of both the object and the observer, and the valence of the object (see e.g., Vagnoni, Lourenco, & Longo, 2012). Recently, it was shown that participants underestimated the distance to objects in frontal space when they were sitting in a car as compared to when sitting in a chair with a similar occlusion of the visual field (Moeller, Zoppke, & Frings, 2015). The participants in this study underestimated distances even more after driving the car for about 10 minutes, but not after walking the same amount of time. This may not be surprising because the faster one is driving, the shorter the time it takes for an object to reach the car. To maintain a similar safety boundary around the body at higher speeds of movement through the environment, larger distances should be underestimated. The time that is needed to react to events when moving at such high speeds is very important because we are limited in our speed of responding to such events (for example, brake lights illuminating in front of us). Various studies have shown that (multi)sensory warning signals can save precious time by reduce breaking times significantly (e.g., Ho, Gray, & Spence, 2014; Ho, Reed, & Spence,
The findings from studies of crossmodal exogenous spatial attention in depth and audiovisual integration in near versus far space might be relevant in an applied setting as well. For example, it has been shown that auditory cues presented in far space are more effective in attracting an observer’s attention to the correct lateral location in far space than auditory cues that are presented in near space (Van der Stoep, Nijboer, & Van der Stigchel, 2014). Whether this would work similarly under conditions of high cognitive load remains to be seen (e.g., while driving), as previous studies have shown that unimodal cues do not capture attention as effectively under such conditions (see Spence & Santangelo, 2009 for a review). Multisensory cues, however, would appear to be relatively unaffected by the amount of cognitive load in terms of their capacity to attract attention. This property of spatially co-located multisensory cues, and the recent observation of enhanced audiovisual integration in far space (Van der Stoep, Van der Stigchel, Nijboer, & Van der Smagt, in press), suggest that audiovisual warning signals in far space may be especially effective as a warning signal while driving. However, if the speed of driving extends peripersonal space in such a way that stimuli that are far away are still being considered to be within the peripersonal space, then audiotactile or visuotactile warning signals may be much more effective given their relevance in peripersonal space. In fact, such an extension of peripersonal space does not sound very different from the zone of safe travel first suggested by Gibson and Crooks back in 1938. They refer to this zone as “...the field of possible paths which the car may take unimpe
ded”, and it is shaped by objects on or features of the road that need to be avoided or that need to be
approached\(^4\) (Gibson & Crooks, 1938, p. 454). Interestingly, they also made the prescient suggestion that this zone can dynamically change in shape and size based on the current driving situation. Peripersonal space has been shown to behave similarly as it can flexibly update depending on the situation at hand as has been shown in various of the studies that have been mentioned in this review.

**Audiovisual interactions in different depth planes**

In the previous sections, we discussed how multisensory interactions involving the sense of touch are dependent on the distance between stimuli and different parts of the observer’s body. Audio- and visuo-tactile interactions are especially enhanced within peripersonal space. In contrast, one might have expected that the distance from which information is presented modulates audiovisual interactions differently when no tactile consequence is anticipated. Unfortunately, however, less is known about how audiovisual integration is affected by changes in distance. Although audiovisual stimuli can obviously have consequences when approaching the body (think only of the sight and sound of a car driving rapidly towards you; we are thinking here, for example, of those studies that have presented looming audiovisual stimuli, see Cappe, Thelen, Romei, Thut, & Murray, 2012; Cappe, Thut, Romei, & Murray, 2009), the interaction, or integration, of sound and light *per se* does not seem to be any more pronounced in peripersonal space than in extrapersonal space (e.g., Van der Stoep, Nijboer, & Van der Stigchel, 2014). Many of the studies in which audiovisual perception has been investigated in different depth planes have focused on audiovisual temporal perception (e.g., Kopinska & Harris, 2004; Lewald & Guski, 2004; Sugita &

\(^4\) This may remind the reader of deviation away and towards distractors during eye-movements and reaching and grasping (e.g., Tipper, Howard, & Jackson, 1997; see Van der Stigchel, Meeter, & Theeuwes, 2007 for a review on eye-movement trajectories).
Suzuki, 2003; see the next section for further discussion on this matter). Besides the delays in arrival time between sound and light that will be introduced as the distance from the observer increases (Spence & Squire, 2003), certain other factors may also play a role in changing audiovisual interactions as well. So, for example, auditory and visual information may be dominant in far space, and information available in far space is often used for orienting and navigation (Previc, 1998). As a result of this sensory dominance, audiovisual integration might be more pronounced in far space. This was indeed what was observed in a recent study of audiovisual integration in near (~80 cm) and far space (~200 cm; Van der Stoep, Van der Stigchel, Nijboer, & Van der Smagt, in press). Specifically, multisensory integration was enhanced for audiovisual stimuli that were presented in far as compared to near space. This enhancement was evident from increased multisensory response enhancement (faster responses to multisensory targets relative to the fastest response to unimodal targets), and an increased amount of race model inequality violation (Gondan & Minakata, in press; Miller, 1982, 1986). The increase in multisensory response enhancement in far relative to near space was, however, only present when the stimuli in far space were not corrected for retinal image size and intensity. Importantly, the increase could not be explained by a change in stimulus efficacy because the same decrease in the size of the retinal image and intensity in near space as in far space did not give rise to enhanced multisensory integration. The effect could also not be explained solely based on the region of space in which the stimuli happened to be presented (i.e., audiovisual dominance in far space), because there was no difference in integration between the near and far space condition when the stimuli were corrected for retinal image size and intensity. Thus, it was concluded that both a decrease in retinal image size and intensity, and the region of space in which information was presented contributed to the observed enhancement of audiovisual integration. Interestingly, the far space condition, which resulted in a significant increase in multisensory integration relative to near space, was
also the condition that would occur most often in daily life. That is, an increase in the
distance between an audiovisual stimulus and an observer going hand-in-hand with a
decrease in stimulus effectiveness (i.e., decreased retinal image size and intensity).

It does not seem plausible that this increased benefit of audiovisual integration would hold
for those distances that are much greater than 2 m, as differences in arrival times of sound
and light will increase and the visual and auditory stimuli will, at some point, eventually
become more difficult to perceive. Indeed, this is what was observed when the amount of
audiovisual integration was compared between 15 m and 1 m (unpublished data, Van der
Stoep & Di Luca, in preparation). At a distance of 1 m, the race model inequality was
violated, but not at a distance of 15 m, indicating that audiovisual response enhancement was
reduced to the level of statistical facilitation at 15 m.

In a recent study of the Colavita visual dominance effect (see Spence, Parise, & Chen, 2011,
for a review), visual dominance was shown to be enhanced in far relative to near space (Yue,
Jiang, Li, Wang, & Chen, 2015). Although currently unknown, it is likely that visual
dominance may increase with distance, contributing to a decrease in multisensory integration
at very large distances. The greater reliability of spatial localization of visual information in
depth relative to sound may hint that this will indeed be the case (e.g., Agganis, Munday, &

However, visual dominance in far space might also depend on the visual angle of stimuli,
causing decreased visual dominance for smaller audiovisual stimuli in far space.

On the basis of the studies mentioned above, it could be argued that there is an increase in
audiovisual integration from near (< 1m) to far space (~2m), and a reduction in audiovisual
integration at larger distances from the observer (15 m). An explanation for an increase from
near to far space might be found in the reliability of the auditory and visual signals at
different distances. Close by, both auditory and visual signals can be perceived clearly. When
the same stimuli are presented further away from the observer, however, the reliability of
these signals will decrease relative to the same signals when presented close by. The benefit
of integrating information that is less reliable might be more pronounced in far space. At very
large distances, however, the stimuli may be very difficult to perceive and hence the benefit
of audiovisual stimulation will once again decrease. That the reliability of sensory
information is taken into account during multisensory integration has been demonstrated in
various studies by now (e.g., Alais & Burr, 2004; Ernst & Banks, 2002). It seems that each
sense is weighted according to its reliability of, for example, estimating a spatial location.
The more reliable an estimate is (i.e., the smaller the variance), the more it will affect the
final multisensory estimate. It will be interesting in future research to see how visual and
auditory reliability changes as a function of distance and how such changes affect
multisensory integration.

Although the previous research suggests an enhancement of audiovisual integration in far
space, there is also some support for the lack of such distance-specific enhancements of
audiovisual interactions. In a study of crossmodal exogenous spatial attention across and
within different depth-planes, the crossmodal cuing effect was found to be dependent on
whether the auditory cue and the visual target were presented in the same depth-plane or not
(Van der Stoep, Van der Stigchel, & Nijboer, 2014). However, this effect of crossmodal
exogenous spatial attention did not differ for those cues and targets that were presented in the
same depth-plane close by (~1.20 m) as compared to far away (~2 m). Considering that the
visual target stimuli were corrected for the size of the retinal image, these results may not be
all that different from those mentioned previously. In the study of audiovisual integration in
near and far space, there were no differences in multisensory integration when the stimuli
were corrected for retinal image size and intensity (Van der Stoep, Van der Stigchel, Nijboer, & Van der Smagt, in press).

These findings therefore indicate that strength of audiovisual interactions is not only affected by whether spatially aligned multisensory stimuli are presented in near or far space, but also by whether the component auditory and visual stimuli are presented at the same distance or not. Thus, the region of space in which information is presented not only affects multisensory interactions involving touch, but also audiovisual interactions.

**Distance-related temporal modulations of audiovisual interactions**

The time it takes for signals to reach the sense organs and to be processed by the brain varies between sensory modalities. For example, the transmission delay of sound vibration is much higher than the one of light energy due to the different speed of conduction in air. As a result, the relative asynchrony of stimulation from a physically synchronous audiovisual event increases proportionally to the distance of the observer (Spence & Squire, 2003). On the other hand, the neural processing of auditory sensory signals has a lower latency than that of visual information (Corey & Hudspeth, 1979; Pugh & Lamb, 1993; Schnapf, Kraft, & Baylor, 1987). It is often assumed that the effect of distance on perceptual latency is primarily attributable to the lower speed of propagation of sound through air. Given this factor alone, there is a certain distance at which sound and light are expected to reach the sensory cortices simultaneously. With such a synchronous neural signal, it is expected that participants would perceive stimuli to appear simultaneous. This distance has been labeled ‘the horizon of simultaneity’ and exists under the assumption that cortical latency is constant (Pöppel, 1988, see Vroomen & Keetels, 2010, for a review on multisensory temporal perception). The horizon of simultaneity has been estimated to lie at a distance between 10-
15 m. This reasoning does not consider that light source distance causes decreased retinal
data, lower stimulus energy at the retina, and a lower auditory intensity, which might increase
the neural latency of vision, but also that of audition. Therefore, the horizon of simultaneity
might not be very relevant in a real-life setting. A recent study by Di Luca and Warnes (in
preparation) examined whether the distance of a light source from an observer would affect
perceived simultaneity in an audiovisual temporal order task for audiovisual stimuli presented
at arm’s length or at a distance of 16 m. Importantly, whereas sounds had equal loudness at
the speaker, in different conditions, the size and intensity of the light source were either
maintained constant as a function of distance, or they were corrected to have equal visual
angle and stimulus intensity at the observer vantage point. Comparing the results of these two
conditions demonstrated that the optical changes due to the distance of the light source
affected the perception of audiovisual simultaneity. This effect was greatest when the two
distances from which the lights were presented was randomized across trials, presumably
causi7ng the participants to divide their attention to several locations in depth and to view the
stimuli peripherally. As a result, visual latency increased even further. On the other hand, the
perceived simultaneity did not change as a function of visual distance by maintaining
foveation of visual stimuli with equal retinal size and perceived luminosity. These results
therefore indicate that not only the distance of the auditory source, but also that of the visual
source affects perceived simultaneity. Therefore, the horizon of simultaneity is only
attainable at the proposed distance of 10-15m if visual stimuli are compensated for retinal
size and energy, whereas in a real-world situation the horizon of simultaneity might be farther
than previously thought, or might not exist at all, especially when visual stimuli have limited
spatial extension.

Social factors relevant to peripersonal space
A good example of how social factors can affect how we represent the space around us comes from a study of personal space conducted by Felipe and Sommer back in 1966. These researchers observed that there is a certain distance between individuals that is needed to feel comfortable. When this space is ‘invaded’, the participants (patients in this study) tended to increase the distance, make a barrier, or else flee from the situation. In this way, the authors effectively demonstrated that there is a region of personal space that has a certain boundary and that, when invaded, can evoke discomfort (see also Hall, 1966; Hediger, 1955). Thus, in terms of behavioral outcome, the space around these participants was automatically divided into two different regions: a personal, and a non- or extrapersonal region of space. Various factors can affect the distance or size of the personal space, such as the cultural background, the nature of the relationship between people, the status of people, the layout of the environment, etc. (see Burgoon & Jones, 1976, for a review; Gallace & Spence, 2004).

Support for the notion that social factors play a role in coding peripersonal space comes from studies that investigated peripersonal hand space representations of self and others. In the ventral premotor cortex (PMv), the peripersonal hand space does not only seem to represent the space around one’s own hand, but also that of others as seen from a first person perspective (e.g., Brozzoli, Gentile, Bergouignan, & Ehrsson, 2012; Ishida, Nakajima, Inase, & Murata, 2010). What is more, whether an action is viewed from a first or third person perspective has also been shown to modulate action representations in PMv (Oosterhof, Tipper, & Downing, 2012). By contrast, viewpoint-independent coding of peripersonal hand space was observed in parietal and occipitotemporal cortex. These studies would therefore seem to suggest that peripersonal space representations may also play a role in social interactions.

Teneggi et al. (2013) proposed a link between personal space as studied in social psychology context and peripersonal space, as described in neuroscience, by investigating how social
factors modulate the size of peripersonal space. In particular, they tested whether
peripersonal space changes in size depending on the presence of another individual, and on
whether the other individual was cooperative or non-cooperative with the participant
(Teneggi, Canzoneri, di Pellegrino, & Serino, 2013). The size of peripersonal space was
assessed in terms of the distance at which approaching sounds started to decrease
participants’ detection latencies in response to tactile stimuli delivered to the their face (see
also Noel et al., 2015). Two main findings were obtained: First, the mere presence of an
unknown person shapes peripersonal space representations, since the boundary of
peripersonal space was closer to the participants when they faced another individual as
compared to when they faced a mannequin instead, as if people automatically and implicitly
divide the space between themselves and others (see, for related effect of active presence,
Heed et al., 2010). Even more interestingly, the size of peripersonal space was found to
increase after playing an economic game with a cooperative individual who was positioned in
front of the participant as compared to before playing the economic game (and this was not
the case when the game was played with an uncooperative individual). This enlargement of
one’s own peripersonal space so as to include the space around the cooperative other was
interpreted as a sharing of self-other peripersonal spaces after positive social interactions.

When thinking of the function of maintaining a certain interpersonal distance, not only does
the feeling of safety come to mind, but also the maintaining of bodily integrity (see Iannetti,
& Mouraux, 2010; Melzack, 1999; Moseley, Gallace, & Spence, 2012;). To do so, it is
essential to avoid harm, to update a body representation, and monitor potential sources of
threat in relation to the body. Several recent studies have investigated how (perceived) threat
affects sensory processing in peripersonal space. For example, the size or shape of the
defensive peripersonal space has recently been shown to be related to trait anxiety (Sambo &
Iannetti, 2013; de Vignemont & Iannetti, 2015). Other researchers, meanwhile, have reported
that the size of PPS is correlated with the extent of claustrophobic fear (Lourenco, Longo, & Pathman, 2011; see Taffou & Viaud-Delmon, 2014, for the relation between cynophobic fear and peripersonal space; see also Dosey & Meisels, 1969). The distance from the body at which auditory stimuli start to affect RTs to tactile targets on the hand is also larger for auditory stimuli with negative compared positive valence. This could be interpreted as an extension of the safety zone or the peripersonal space for threatening or negative stimuli (Ferri et al., 2015).

Interestingly, in these studies, the tactile stimuli that were delivered were not necessarily painful. A recent study investigated whether visual information in peripersonal space could affect the processing of specifically nociceptive stimuli (De Paepe, Crombez, Spence, & Legrain, 2014). Unilateral visual cues were presented to the left or the right side of space before the onset of two nociceptive stimuli. Using a temporal order judgment task with nociceptive stimuli delivered to the left and right hand, unilateral visual cues presented in peripersonal space were shown to affect the perceived point of subjective simultaneity more than those visual cues that were situated in extrapersonal space. These results therefore indicate that the interaction between visual and nociceptive stimuli also depends on the region of space in which visual information is presented. The proximity of threat also seems to affect distance estimation of stimuli relative to the body (see Tabor et al., 2015). When participants had to estimate the distance between their body and a switch that was associated with threat (i.e., a nociceptive stimulus delivered to the hand), they generally underestimated the distance as compared to a switch that was associated with relief. Overall, then, the results from these studies clearly indicate that threat and pain perception (or prediction) affect multisensory spatial processing.
General Discussion

There has been an enormous increase in studies of multisensory integration in recent years. However, one aspect of multisensory perception that has received less attention than others is the depth or distance from which information is presented. The studies that looked at how the distance at which information is presented affects multisensory integration have primarily investigated multisensory interactions in peripersonal space and multisensory temporal perception. In the present review, we highlight how these studies have contributed to our understanding of multisensory perception, but their scope was limited, as the stimuli used have been presented from a relatively limited region of space. That is, studies of multisensory processing have focused in a narrow region of space in front of the observer (see Figure 2). Furthermore, it seems we are at a point where we would benefit from studying multisensory interactions in more dynamic situations such as when the observer and the stimuli are moving in relationship between each other in a more complex, ecological environment. This will allow us researchers to gain a better understanding of how multisensory integration takes place when those factors, which frequently change in our daily lives, are taken into account (e.g., the distance between stimuli and the body, movement of the body, moving stimuli). A schematic overview of a change in peripersonal space representation by the factors that are discussed in this review can be found in Figure 3.

[Insert Figure 3 about here]

A framework that might prove helpful when it comes to thinking about how the brain deals with multisensory interactions that are changed by, for example, movement of the body or
movement of stimuli is the predictive coding framework (e.g., Friston, 2005; Friston & Kiebel, 2009; Clark, 2013). According to this framework, predictions about the state of the world through our senses are adjusted via feedback in the form of prediction errors by a constant interaction between bottom-up and top-down information. This idea fits well with the observation that multisensory experience with the environment is essential to the development of multisensory neurons and therefore to multisensory integration (e.g., Wallace, Perrault, Hairston, & Stein, 2004; Wallace & Stein 2007). The brain receives information about the world and the state of the body in that world through multiple senses. Each sense provides information about the world in a different way (e.g., in different reference frames) with different qualities (e.g., different spatial and temporal resolutions). This allows the brain to calibrate information from one sense with information from another sense (e.g., King, 2009; Shams, Wozny, Kim, & Seitz, 2011). Such multisensory calibration allows maintenance of multisensory spatial representations on a daily basis, given that the world around is always readily available. As such, it is not unthinkable that the brain calibrates in such a way that interactions between the senses become spatially dependent. For example, given that there is a strong correlation between visual and tactile sensations of stimuli near the hand in real life, visual stimuli near the hand interact more strongly with tactile stimulation than visual stimuli far from the hand.

To conclude, in order to gain a better understanding of how humans interact with the abundance of multisensory information in the environment, it seems essential to investigate multisensory integration in three spatial dimensions. The contribution of each of our senses to our perception of and our interactions with the world depends on the region of space in which information is presented (e.g., front vs. rear, peripersonal vs. extrapersonal space). An important next step towards unraveling multisensory integration in everyday situations may be to investigate how multisensory interactions change online in dynamic situations such as
while moving (e.g., walking, driving), when perceiving moving stimuli, and their combination in 3-D space.
