Abstract

Background. Sjögren’s syndrome and systemic lupus erythematosus (SLE) are related by clinical and serological manifestations as well as genetic risks. Both diseases are more commonly found in women compared to men at a ratio of about 10 to 1. Common X chromosome aneuploidies, 47,XXY and 47,XXX, are enriched among men and women, respectively, in either disease suggesting a dose effect on the X chromosome.

Methods. We examined cohorts of Sjögren’s syndrome or SLE patients with intensity plots of X chromosome single nucleotide polymorphism (SNP) alleles along with karyotype of selected subjects.

Results. Among ~2500 women with SLE we found three patients with a triple mosaic consisting of 45,X/46,XX/47,XXX. Among ~2100 women with Sjögren’s syndrome, one patient had 45,X/46,XX/47,XXX with a triplication of the distal p arm of the X chromosome in the 47,XXX cells. Neither the triple mosaic nor the partial triplication were found among controls. In another Sjögren’s cohort, we found a mother-daughter pair with partial triplication of this same region of the X chromosome. The triple mosaic occurs in approximately 1 in 25,000 to 50,000 live female births, while partial triplications such are even rarer.

Conclusions. Very rare X chromosome abnormalities are present among patients with either Sjögren’s or SLE, and may inform the location of a gene(s) that mediate an X dose effect as well as critical cell types in which such effect is operative.
Introduction

Systemic lupus erythematosus (SLE) and Sjögren’s syndrome are related by common autoimmune serology, clinical manifestations, and genetics, as well as a strong bias towards the female sex. The sex bias for SLE is about 10-to-1\(^1\), while among those with Sjögren’s, women are over-represented between 10 and 15-fold.\(^2\)

Aneuploidies of the X chromosome are common in the human population. Klinefelter’s syndrome (male 47,XXY) occurs in about 1 in 500 live male births but 80% of these men are undiagnosed.\(^4\) Meanwhile, 47,XXX is found in about 1 in 1000 live born girls with only about 1% identified.\(^5,6\) We have found excess 47,XXY among men with either SLE\(^7,8\) or Sjögren’s syndrome\(^9\) as well as excess 47,XXX among women with these diseases.\(^10\) On this basis, we have proposed an X chromosome dose effect for the sex bias of SLE and Sjögren’s syndrome. Such a bias might be mediated by specific genes that escape X inactivation, global escape of X inactivation in specific cell types\(^11\) or interference with immune tolerance by increased production of X chromosome gene products\(^12\), or an effect on the immune system by the mosaicism of random X inactivation.\(^13\)

We have previously reported a 46,XX man among 316 men with SLE.\(^14\) This X chromosome abnormality occurs in as few as 1 in 25,000 to 1 in 50,000 live born boys. We undertook the present study to examine women with either SLE or Sjögren’s syndrome for rare X chromosome aneuploidies.

Methods

Subjects. We studied a large cohort of SLE patients with about 60% being of European heritage and 40% of African heritage, gathered for genetic and other studies, which has been described in detail\(^15\) as well as a large cohort of primary Sjögren’s syndrome patients, where all subjects meeting criteria for other
autoimmune rheumatic disease (that is, those with secondary Sjögren’s were excluded). Subjects met the respective research classification criteria for each of the diseases. Women demonstrated to not have SLE or Sjögren’s served as controls. As previously described, controls were screened for autoimmune rheumatic disease, and no such disease was identified.

X chromosome Analyses: The subjects were screened for X chromosome abnormalities by examination of intensity plots of X chromosome single nucleotide polymorphism (SNP) alleles, as we have previously described. In these displays (so-called, b plots) the fluorescent intensity of the b allele is divided by the intensity of the a and b alleles; thus, giving values of 1.0 for homozygous b SNPs, 0.5 for ab heterozygous SNPs and 0.0 for homozygous a SNPs. However, a person with three X chromosomes will have b plot results at 0.33 for aab SNP alleles and 0.67 for abb alleles. Subjects with abnormal b plots were then studied by karyotype of peripheral blood mononuclear cells, or fluorescent in situ hybridization (FISH), as previous described. Some subjects were studied directly with karyotype using standard methods in a Clinical Laboratory Improvements Amendments (CLIA)-approved laboratory.

Statistics. We calculated binomial 95% confidence intervals for ratios. To calculate the prevalence of SLE among individuals with X triple mosaic, we used Bayes’ theorem as previously described. Briefly,

\[ P(B/A) = P(A/B) \times \frac{P(B)}{PA} \]

where \( P(B/A) = \) prevalence of SLE among those with the triple mosaic, \( P(A/B) = \) prevalence of the triple mosaic among SLE patients, \( P(B) = \) prevalence of SLE in the population, and \( P(A) = \) prevalence of the X triple mosaic in the population.

Results
Among 2,426 women with SLE, we found three with the rare triple mosaic of 45,X/46,XX/47,XXX based on the b plots; these results were confirmed by G-band karyotyping of 50 cells (Table 1). These SLE patients had approximately the same ratio of cells with the abnormal X chromosome number. Namely, only 3% of cells were either 45,X or 47,XXX, while a large majority (~94%) carried 46,XX. In examination of their clinical records, there was no diagnosis nor clinical evidence of Turner’s syndrome, abnormal sexual development, or infertility. Binomial 95% confidence intervals for the ratio 3 in 2,426 (0.0012 or 1 in 809) were 0.0003 to 0.0036 (or 1 in 3333 to 1 in 278). And, therefore, did not include the estimated birth rate of 45,X/46,XX/47,XXX of 1 in 25,000.\textsuperscript{5,20,21} Thus, we concluded that there is a statistical increase in the prevalence of the X chromosome triple mosaic among SLE patients.

We used Bayes’ theorem to calculate the prevalence of SLE among women carrying the X triple mosaic. For this calculation we assumed a prevalence for SLE of 1 in 1000 along with a prevalence of the X triple mosaic of 1 in 25,000. The calculation predicted that 1 in 32 individuals with 45,X/46,XX/47,XXX will have SLE.

Among 2138 women with Sjögren’s syndrome we did not find a subject with the X chromosome triple mosaic described above. Instead, when examining X chromosome b plots, we noted a single subject with a partial triplication of the X chromosome p arm. That is, distal Xp showed 4 intensity bands at 0.0, 0.3, 0.6 and 1.0, indicating three copies of this portion of the X chromosome, but other areas of the X chromosome showed only three bands at 0.0, 0.5 and 1.0. The latter is the pattern for two X chromosomes (Figure 1A). We obtained a blood sample from this subject and performed karyotyping, which showed a triple X chromosome mosaic with 2 of 20 (10%) cells examined carrying 45,X and 13 of 20 (65%) cells carrying 46,XX, while 5 of 20 (25%) of cells had a triplication of the distal portion of the p arm of X (see Figure 1B). This additional, triplicated portion of X consisted of a non-reciprocal
translocation on to one of the X chromosomes, that is, 47,XX<sup>XP</sup>. By karyotype this abnormality was designated 45,X/46,XX/46,X,der(X)(pter>q28::p11.4>pter) (Figure 1).

We have identified another Sjögren’s patient with a rare X chromosome abnormality in a United Kingdom Sjögren’s cohort. The patient was studied by karyotype as a child based on the presence of epilepsy, oligomenorrhea, and thyroid dysfunction. This study showed one normal X chromosome and one isochromosome Xp, that is, an X chromosome with 2 p arms (Figure 1C). Her mother had an inverted segment of Xq (Figure 1C). Both the mother and daughter have Sjögren’s syndrome. This entire cohort of 940 Sjögren’s patients has not been systematically studied for X chromosome abnormalities as approximate 700 are included among the 2138 studied above. So, while the identification of this partial triplication of Xp must be considered anecdotal, the triplicated region overlaps with the one found among the systematically studied patients (Figure 1C). Thus, this incidentally found X chromosome abnormality supports the idea that a gene or genes within distal Xp mediate the X chromosome dose effect.

We found no control subject (n=2712) with the X chromosome triple mosaic, or any variant thereof (Table 1).

Discussion

SLE and Sjögren’s syndrome, similar to many other autoimmune diseases, have a marked sex bias with women affected about 10 times more often than men. A number of hypotheses have been proposed, and some of these tested, to explain the marked sex bias in these diseases. An obvious difference is sex hormones, which might include not only estrogen, androgen and progesterone but also prolactin. 22
Several estrogenic effects, including differentiation of T helper cells, induction of interferon, and survival of B cells, may predispose to autoimmune disease\textsuperscript{23} as well as recently described effects on the AIRE gene.\textsuperscript{24} A counterargument to the hormone hypothesis is that sex hormones are within normal limits at the time of SLE diagnosis\textsuperscript{25, 26} and are not different between men with SLE and men with other chronic, non-autoimmune disease.\textsuperscript{27} However, men with untreated hypogonadism are reported to be at high risk of SLE.\textsuperscript{28} There is no evidence of acquired X monosomy among women with SLE\textsuperscript{29, 30}, as there is among those with autoimmune thyroid disease\textsuperscript{31} or primary biliary cirrhosis.\textsuperscript{32}

Failure to inactivate an X chromosome in activated CD4+ T cells is found in SLE patients\textsuperscript{33-35} and lupus-prone mice\textsuperscript{36} with failure to methylate; and, thus silence, X-linked immune genes.\textsuperscript{37} A recent study has shown a global difference in X chromosome inactivation in resting lymphocytes, which was associated with bi-allelic expression of genes from lymphocytes of SLE patients.\textsuperscript{11} Others have proposed that an overall effect of X reactivation might perturb immune tolerance.\textsuperscript{12} Each of these proposed mechanism might underlie a gene dose effect on the X chromosome, which might involve one or more immune-related proteins encoded on the X chromosome.

We have found very rare X chromosome abnormalities among patients with either SLE or Sjögren’s syndrome. Based on karyotypes of consecutive live births,\textsuperscript{5, 20, 38} the 45,X/46,XX/47,XXX triple mosaic is found in about 1 in 25,000 live born girls, but was present in about 1 in 800 women with SLE. We did not find and did not expect to find the rare triple mosaic among our controls, which number only just above 2000. But, past studies of more than 25,000 live female births\textsuperscript{5, 21, 38} serve as an external validation of the incidence and prevalence of the 45,X/46,XX/47,XXX mosaic. Meanwhile, the 45,X/46,XX/47,XX\textsuperscript{Xp} found in one of our Sjögren’s syndrome patients is nearly unprecedented.\textsuperscript{39}
Finding these X chromosome rarities has several implications. For instance, only a small percentage of cells carried the additional X or portion of the X chromosome in these patients. The data from Wang, et al. are consistent with this finding as the unusual maintenance of X chromosome inactivation in lymphocytes leads to bi-allelic expression of X-linked genes in only a few cells.\textsuperscript{11} In addition, similar to those with 100% of cells carrying 47,XXX\textsuperscript{10}, the 4 patients we described have no evidence of abnormal sex hormones or sexual development. Likewise, hormonal imbalance due to Turner’s syndrome, which is likely under-represented among SLE patients\textsuperscript{7}, is not expected with the low proportion of 45,X cells in our patients. Thus, estrogen, progesterone, or androgen differences cannot be evoked as an explanation of the apparent association of the X triple mosaic with SLE and Sjögren’s syndrome.

Despite the associations we find, increased prevalence of these rare X chromosome aneuploidies does not prove causality. Nonetheless, given the rarity of these X chromosome abnormalities, association by chance alone seems unlikely to us. Determining mechanism by which additional X chromosomes or distal Xp fragments, increase the risk of these diseases remains to be determined, but will provide evidence of causality. Perhaps the findings reported herein give important clues, which can be used to direct and narrow the candidates for genes impacting the X chromosome dose effect. The distal p arm of the X chromosome contains multiple genes that escape X inactivation.\textsuperscript{11} Thus, the finding of a partial trisomy of this portion of the X chromosome in these patients suggests, but does not prove, that the gene or genes mediating this effect are found in this region. There are a number of past examples in which identification of an abnormality on karyotype in an affected individual led to much more rapid identification of the genetic cause of a particular disease. These include Duchenne’s and Becker’s muscular dystrophy, Angelman’s syndrome, and fragile X syndrome. But, perhaps relevant to the findings herein, was the identification of a chromosome X-21 balanced transloction in a girl with
Duchenne's muscular dystrophy. This finding gave the location of the gene on the X chromosome long before identification was possible through reverse genetics studies. In summary, we suspect that these SLE and Sjögren’s with X chromosome abnormalities inform greatly about the common situation, that is, the marked sex bias between 46,XX women and 46,XY men. Future studies, using the localization provided by the very rare patients reported herein, may be able to concentrate on genes within this shared triplicated region of Xp as the mediators of the X chromosome dose effect for sex bias in SLE and Sjögren's syndrome.
