Abstract

The majority of the world’s children grow up learning two or more languages. The study of early bilingualism is central to current psycholinguistics, offering insights into issues such as transfer and interference in development. From an applied perspective, it poses a universal challenge to language assessment practices throughout childhood, as typically-developing bilingual children usually underperform relative to monolingual norms when assessed in one language only. We measured vocabulary with Communicative Development Inventories for 372 24-month-old toddlers learning British English and one Additional Language out of a diverse set of 13 (Bengali, Cantonese, Dutch, French, German, Greek, Hindi-Urdu, Italian, Mandarin, Polish, Portuguese, Spanish and Welsh). We furthered theoretical understanding of bilingual development by showing, for the first time, that linguistic distance between the child’s two languages predicts vocabulary outcome, with phonological overlap related to expressive vocabulary, and word order typology and morphological complexity related to receptive vocabulary, in the Additional Language. Our study also has crucial clinical implications: we have developed the first bilingual norms for expressive and receptive vocabulary for 24-month-olds learning British English and an Additional Language. These norms were derived from factors identified as uniquely predicting CDI vocabulary measures: the relative amount of English versus the Additional Language in child-directed input and parental overheard speech, and infant gender. The resulting UKBTAT tool was able to accurately predict the English vocabulary of an additional group of 58 bilinguals learning an Additional Language outside our target range. This offers a pragmatic method for the assessment of children in the majority language when no tool exists in the Additional Language. Our findings also suggest that the effect of linguistic distance might extend
beyond bilinguals’ acquisition of early vocabulary to encompass broader cognitive processes, and could constitute a key factor in the study of the debated bilingual advantage.
Vocabulary of 2-Year-Olds Learning English and an Additional Language: Norms and Effects of Linguistic Distance

Chapter 1 – Introduction

Parents eagerly await the moment their one-year-old infant produces their first word, and professionals working with young children track the appearance of the two-word combination stage at around age 2. To developmental psycholinguists, these two milestones in healthy language acquisition are supported by an impressive range of achievements, from the attuning of perceptual abilities (Werker, Yeung, & Yoshida, 2012), the development of word segmentation skills (Bergmann & Cristia, 2016) and the retrieval of word meaning (Stevens, Gleitman, Trueswell, & Yang, 2017), to the discovery of syntactic, morphological and conversational rules (Gleason & Ratner, 2017; Hoff, 2013). The complexity of the task that young children naturally solve places the study of language development at the heart of the debate about the nature of the human mind (Pinker, 1995; Tomasello, 2009). In addition, the co-occurrence - and interdependence - of language development and that of other domains such as motor coordination (Iverson, 2010), object perception (Jones & Smith, 2005), or social skills (Carpenter, Nagell, Tomasello, Butterworth, & Moore, 1998), indicates that the study of language learning is fundamental to the understanding of child development as a whole.

Even more impressive than an infant acquiring her maternal language is an infant learning two or more languages, an achievement of the majority of the world’s children (Kohnert, 2010), including an increasing proportion in the United Kingdom (UK) (17.5% in primary schools; NALDIC, 2012). Although knowledge about language development is mostly built around the monolingual child model, the study of early bilingualism has become a central issue in psycholinguistics. This is because it allows us to address theoretical key
questions such as specificity, differentiation, transfer and interference in development, but also because, from an applied perspective, it poses a universal challenge to language assessment practices throughout childhood. Indeed, language development in bilinguals is notoriously difficult to predict, due to a variety of situational factors related to the proportion and properties of dual-language exposure, making the use of monolingual norms largely inadequate for this population (Cattani et al., 2014). This is further complicated by the variety of language pairs being spoken in the world. For example, in the United States (US), whilst Spanish constitutes the most common other-than-English language spoken at home (62% speakers), the remaining 38% speakers share up to at least 350 languages, mostly in large metropolitan areas (United States Census 2020). Given the mounting evidence that children develop their two languages in separate, yet interfering, systems (Hoff, 2013), the degree of influence between two languages should theoretically depend upon the linguistic distance between the two languages.

The central aim of this paper is to investigate the role of linguistic distance in early language development, and through this, we address two key questions: first, we bring new theoretical knowledge by directly testing hypotheses regarding the existence of language-to-language influence in early bilingual development; second, we offer a pragmatic solution to the widespread problem of how to assess bilingual toddlers’ language skills when no tools are available in the home language. Although the study was conducted in the UK, the theoretical conclusions we reached about the role of linguistic distance are not community-specific, and the principles behind the assessment tool we have designed can be exported to any other community.

We collected data about vocabulary development and contextual variables in a cohort of 372 bilingual two-year-old toddlers learning British English and one of 13 Additional Languages. We investigated how vocabulary development is modulated by linguistic distance
between British English and the Additional Language, bringing new evidence about language-to-language influence in early acquisition, and the first demonstration to date of an effect of structural similarity between languages on early vocabulary development (Study 1). In addition, we generated a vocabulary model able to predict the lexicon size of 2-year-old bilinguals in English and one the 13 target Additional Languages, which fed into a new assessment tool, the UKBTAT (UK Bilingual Toddler Assessment Tool) (Study 2). Finally we showed that this model could reliably predict the English scores of a new cohort of 58 British-English 2-year-olds learning a new, non-target Additional Language (Study 3). In what follows, we review the literature pertaining to the theoretical (Study 1) and applied contributions of this work (Studies 2 and 3). In Chapter 2 we present the methods for the cohort data collection, followed by the analyses pertaining to Study 1 in Chapter 3, Studies 2 and 3 in Chapter 4, ending with Chapter 5 where we discuss how linguistic distance shapes language development and the limiting factors of this work.

**Study 1: Understanding the Role of Linguistic Distance in Bilingual Development**

Most bilingual studies are conducted with homogeneous samples, with Spanish-American English bilinguals constituting the largest cohort (e.g., Marchman, Fernald, & Hurtado, 2010; Place & Hoff, 2011), followed by Canadian English-French (e.g., Paradis, Crago, Genesee, & Rice, 2003), Barcelona Catalan-Spanish (e.g., Bosch & Sebastián-Gallés, 2001) and Welsh-British English (e.g., Gathercole & Thomas, 2009). Although it is often reasonable to generalise results obtained with one language pairing to different language pairs, is it safe to assume that bilingual children from different backgrounds are confronted with the same linguistic problems to solve, or that they are able to solve them within the same learning span?

There is growing evidence that, according to the language they acquire, monolinguals’ learning paths can differ, including for early lexical prosodic processing (Adam & Bat-El,
word segmentation (across dialects: Floccia et al., 2016; Nazzi, Mersad, Sundara, Iakimova, & Polka, 2014), and phonological processing (Nazzi, Floccia, Moquet, & Butler, 2009; Mani & Plunkett, 2007; Delle Luche, Floccia, Granjon, & Nazzi, 2016; Bouchon, Floccia, Fux, Adda-Decker, & Nazzi, 2015), culminating in differences in vocabulary growth (Bleses et al., 2008; Thordardottir, 2005). Bilingualism is likely to exacerbate these language-specific differences, adding not only a new language but also the complexity of interactions between languages.

Why should we expect interactions between the two language systems in a bilingual child? In adult bilinguals, evidence for automatic cross-language activation in visual word recognition (Lauro & Schwartz, 2017), and in spoken word recognition (Mercier, Pivneva, & Titone, 2014; Spivey & Marian, 1999) strongly point to the interdependence of the two language systems (see French & Jacquet, 2004). A common position nowadays, following the original proposal of a primary, undifferentiated language system (Volterra & Taeschner, 1978), is that early bilinguals develop two independent language systems (Genesee, 1989; Genesee, Nicoladis, & Paradis, 1995). However, accumulating evidence suggest early influences from one language system onto the other, mirroring the structure of the adult system. Interaction between the two language systems is perhaps most obvious in production, where intra-sentential code-mixing, i.e., including elements of each language at the sentence level, is frequently observed in toddlers at the phonological, lexical and morphosyntactic level (e.g., Gildersleeve-Neumann, Kester, Davis, & Peña, 2008; Paradis & Genesee, 1996). More convincing however is non-selective lexical access in comprehension, that is, the fact that speech presented in one language activates word recognition in the two languages, as demonstrated in adults (e.g., Dijkstra, 2005), and observed at least as young as from three years of age (e.g., Poulin-Dubois, Bialystok, Blaye, Polonia, & Yott, 2013; Von Holzen & Mani, 2012; see the review by DeAnda, Poulin-Dubois, Zesiger, & Friend, 2016). However,
even if there were an initial separation of lexicons, bilinguals would still demonstrate language-specific differences from the parallel learning of two language systems. For example, French infants rely more on consonants than vowels for lexical processing from the age of 8 months (Nishibayashi & Nazzi, 2016), whereas British English learners process consonants and vowels equally (Mani & Plunkett, 2007; Floccia, Nazzi, Delle Luche, Poltrock, & Goslin, 2014), at least until the age of 30 months (Nazzi et al., 2009), and Danish children rely more on vowels than consonants at 20 months of age (Højen & Nazzi, 2016). How do such differences translate to the case of bilingual learners? Will language-specific routes for vowel-consonant processing be delayed until the onset of separate language processing, or will one linguistic strategy be adopted, at an efficiency cost to the other language?

In sum, each language pairing will necessarily produce a different linguistic learning problem for bilingual infants to solve, which is likely to translate to variable delays and/or adapted pathways (see Polka, Orena, Sundara, & Worrall, 2017, for word segmentation outcomes differing in bilingual and monolingual 8-month-olds). In this project we conducted the first systematic evaluation of the impact of differences between languages, as measured through metrics of linguistic distance, on vocabulary acquisition in both British English and the Additional Language.

**Measuring linguistic distance.** As adults, second language learning seems easier if the language is intuitively similar to our own (e.g., English/German vs English/Cantonese), which is supported by studies in second language learning for both adults and school-aged children (e.g., Lado, 1957; Lindgren & Muñoz, 2012; Van der Slik, 2010). For example Lindgren and Muñoz (2012) showed that a cognate-based measure of language distance is the most important predictive factor for formal second language learning in schools, above differences in the exposure of the languages at home. These results support the idea that in
second-language learning, the knowledge and structure of L1, i.e. the maternal language, provide scaffolding for the acquisition of L2, i.e. the Additional Language (see also the literature on cross-linguistic transfers in second language reading acquisition, e.g., Genesee, Geva, Dressler, & Kamil, 2006).

However, in early simultaneous bilinguals the effects of language distance are more complex as the languages are acquired in parallel from infancy. While similarities between the two languages may reinforce phonological, lexical and syntactic acquisition across the two languages, it would also reduce the perceptual separation between languages. Knowledge of the interaction between reinforcement and separation is crucial to our understanding of bilingual acquisition, but the complexity of multi-dimensional representations of language means that unitary measures of the seemingly intuitive notion of ‘linguistic distance’ are difficult to evaluate. This complexity is reflected in the many distance metrics which have been proposed, including cognate distance (e.g., Dyen, Kruskal, & Black, 1992), genetic linguistic distance (Harding & Sokal, 1988; Ruhlen, 1987), phonetic distance (Nerbonne et al., 1996), distance in terms of linguistic rhythm (Ling, Grabe, & Nolan, 2000; Ramus, Nespor & Mehler, 1999) and second language learnability (Chiswick & Miller, 2005).

Of all linguistic distance measures, cognate distance is probably the metric that has the widest currency, at least at the lexical level. Traditionally, this refers to the proportion of translation equivalents sharing common historical origins, such as lait in French and leche in Spanish (milk, sharing the Latin root lac). In an influential cognate database (e.g., Dyen et al., 1992, adapted by McMahon & McMahon, 2005), the index of linguistic cognate distance is obtained from the compilation of 200 frequent culture-neutral words in 84 Indo-European languages and dialects, and for each language pairing. However, the definition of cognates in Dyen et al.’s database makes it difficult to generalise to languages without a clear common history. Approaches based on automatic methods have been proposed to refine the definition
of cognates, for example by using intra-language similarity (Ellison & Kirby, 2006) or cross-
language orthographic similarity measures (Serva & Petroni, 2008). While some of these
metrics may be suitable for the adult speech environment, child-directed speech differs in
lexical, prosodic and pragmatic content from adult-directed speech (e.g., Thiessen, Hill, &
Saffran, 2005). Importantly, infants do not share adults’ meta-linguistic and orthographic
knowledge.

Given the young age of our participants it was necessary to base our distance metrics
on a set of child-familiar basal words and to consider phonetic, phonological and metrical
similarities rather than historical origins or orthographic properties. To this end we developed
a measure of linguistic distance which focussed upon corpora related to toddlers’ speech
environment. We used the Oxford Communicative Developmental Inventory of Oxford CDI
(Hamilton et al., 2000), which supplied us with a list of words that should be known to
British English children of our target age group. Here a short introduction to the CDIs is
necessary, as we will use these tools not only to develop a metric of phonological overlap, but
also to collect vocabulary data from toddlers.

The first Communicative Developmental Inventories, which are parental reports of
their children’s vocabulary on a checklist of familiar words, were developed for American
English children (Fenson et al, 1994), with norms published in two separate forms for
different age ranges (8-18 months for the Words and Gestures form, and 16-30 months for the
Words and Sentences form). An updated norming sample of 2,550 US children was produced
later for the two forms (MacArthur-Bates CDI, Fenson et al., 2007). Crucially, the normed
CDI parent reports have been adapted (not translated) in a multitude of languages, with the
purpose of mirroring the structure of the reference language as much as possible. The
availability of CDIs in many languages has created new opportunities for cross-linguistic
studies of language development (see e.g., CLEX database now called Wordbank: Jørgensen,
Dale, Bleses, & Fenson, 2009; Frank, Braginsky, Yurovsky, & Marchman, 2017) and for bilingual studies (e.g., Armon-Lotem, & Ohana, 2017; Cattani et al., 2014; Gatt, 2017; Pearson, Fernandez, & Oller, 1993; O’Toole et al., 2017). The reliability and validity of CDIs is long established for use in research (Mancilla-Martinez, Gamez, Vagh, & Lesaux, 2016; Marchman, Thal, Dale, & Reznick, 2006) and for clinical assessment (e.g., Charman, Drew, Baird, & Baird, 2003; Heilmann, Weismer, Evans, & Hollar, 2005; Thal, DesJardin, & Eisenberg, 2007).

To produce vocabularies for the 13 target Additional Languages, we could have used the words listed in each language-specific CDI as a proxy of toddler vocabulary for each Additional Language. However, these CDI vocabularies would largely reflect the cultural and physical environment in which the language was predominantly spoken. As our bilinguals all live in the UK it is likely that both their British English and Additional Language vocabulary would reflect a British English environment, rather than the environment of the monolingual Additional Language CDI. As such, we believe that the bilingual Additional Language lexicon would be better represented by translation equivalents of the words of the Oxford CDI. This approach also has the advantage that it is unaffected by variations in the methodologies used to construct Additional Language CDIs, which can result in wide differences in CDI word counts. Details of these toddler-centric metrics can be found in the method section (Chapter 2). Note that the use of a common CDI inventory across all language groups was restricted to the calculation of a metric of phonological overlap, and not to collect vocabulary knowledge from toddlers, which was performed with language-specific inventories.

With this first metric based on lexical phonological overlap, we expected phonological similarity between languages to facilitate the acquisition of words in each language. This hypothesis is supported by results from Bosch and Ramon-Casas (2014)
showing that 18-month-old Catalan-Spanish bilinguals were more likely to produce highly similar cognates than less similar ones.

In addition to measures of linguistic distance based on lexical overlap, we also ranked language pairs on measures of grammatical distance, namely word order typology and morphological complexity. Languages can be broadly distinguished on the basis of the relative order of the main verb (V) and its object (O) (Dryer, 1991; Greenberg, 1963), with VO order as in English and Spanish, OV as in Bengali and Hindi/Urdu and mixed OV/VO for German and Dutch. Children’s very first combinations of words show knowledge of this basic word order (e.g., Bates et al., 1984; Brown, 1973), demonstrated even earlier in comprehension (e.g., Höhle, Weissenborn, Schmitz, & Ischebeck, 2001), although the full knowledge of native language word order patterns takes several years to develop (e.g., Abbot-Smith, Lieven, & Tomasello, 2008; Akhtar & Tomasello, 1997; Guasti, 2002). To retrieve information about their language’s syntactic typology, monolingual infants have been found to rely on the relative order of function and content words in their first year of life (Gervain, Nespor, Mazuka, Horie, & Mehler, 2008), as well as on prosodic correlates of word order (Bernard & Gervain, 2012; Christophe, Nespor, Guasti, & Van Ooyen, 2003). In bilingual infants, Gervain and Werker (2013) recently showed that when learning languages with opposite word orders, such as English and Hindi, 7-month-old bilinguals would also exploit the appropriate prosodic information, revealing an early sensitivity to cues that can be used to acquire basic word order in their two languages. Once acquired, knowledge of word order would logically boost word segmentation and grammatical parsing, and therefore learning two languages with a common word order might facilitate these processes. We examined whether vocabulary scores in English and in the Additional Language at the age of 2 could be predicted from the similarity of British English and the Additional Language in terms of word order typology.
Finally, languages can also be ranked on a continuum of morphological complexity (Brown, 2010; Comrie, 1989; Greenberg, 1960), with analytic or isolating languages on one end of the continuum (lowest ratio of morphemes to words, as in Cantonese, and to a lesser extent, in English), inflecting/fusional (Russian, Italian, French) as well as agglutinating (Finnish, Basque, Turkish, Hungarian) languages in the middle, and polysynthetic languages on the other end (highest ratio of morphemes to words, such as in Yupik). The most intuitive expectation is that speed of acquisition would vary as a function of the morphological complexity of the to-be-acquired language (see Caselli, Casadio, & Bates, 1999, for this suggestion). Xanthos et al. (2011) found, by contrast, that the more morphologically complex the ambient language, the faster children will acquire morphological rules (see also Leonard, 2000). However, it is possible that the nature of the cognitive resources engaged in language acquisition vary as a function of its morphological complexity, with analytic languages making greater demands on memory than synthetic languages (Fortescue & Lennert Olsen, 1992). In the bilingual situation, acquisition could be boosted when confronted with morphologically close pairs of languages as compared to more distant ones, simply because of a better alignment of cognitive demands. In support for this hypothesis is the study by Paradis (2011) showing that 6-year-old second language learners from immigrant families in Canada had a better command of English verb morphology if their language at home was closer to English in terms of verb morphology typology (marking tense/agreement). Here we evaluated whether vocabulary scores in English and in the Additional Language could be predicted from the proximity of languages in terms of morphological complexity.

**Language community and culture.** In addition to linguistic distance, each language pairing also comes with a range of cultural and social idiosyncrasies, which are impossible to explore exhaustively and often difficult to disentangle from linguistic factors. For example, cultural differences can relate to the degree to which parents communicate with infants
(Bavin, 1992; Brown, 2001), the characteristics of infant-directed speech (Fernald et al., 1989), the degree of focus on objects in conversations (Tardif, Shatz, & Naigles, 1997), parents’ attitude towards bilingualism (De Houwer, 1999), or the level of involvement of siblings in early interactions (Super & Harkness, 2013). Studies which have attempted to examine the combined or separate effects of cultural and linguistic variations in early language development are, to our knowledge, very scarce. One such study by Barac and Bialystok (2012) compared three groups of 6-year-olds on English verbal tasks for receptive vocabulary, grammatical knowledge and metalinguistic awareness, testing Spanish-English, French-English and Chinese-English bilinguals, all attending similar schools in Canada. When controlling for SES and the amount of exposure to each language at home, it was found that Spanish-English bilinguals outperformed French-English and Chinese-English children on verbal tasks. The poorer performance of French-English children was attributed to the fact they were the only group whose schooling was in French – therefore resulting in less exposure to English - whereas the other groups received English schooling. More pertinently, the higher performance of Spanish-English bilinguals as compared to the Chinese-English bilinguals was accounted for by the greater linguistic similarity between Spanish and English than Chinese and English; this was, however, a speculative explanation since the authors acknowledged an unclear understanding of what would constitute cultural differences between these communities. Similarly, Bialystok, Majumber and Martin (2003) showed an advantage for metalinguistic awareness in Spanish-English bilinguals at 6-7 years of age, as compared to English monolinguals, with Chinese-English bilinguals performing worse than both other groups. The authors attributed these differences to English and Spanish being closer in terms of consonant-vowel alternation, as compared to the phonological and tonal structure of Chinese, and also to an advantage of Spanish itself provided by its greater phonological transparency. Once again, however, a combination of cultural and linguistic
factors might explain the differences, for example if one community engaged more in communication overall, or made a greater use of intra-sentential code-mixing.

Disentangling the effect of linguistic distance from that of language community.

It is impossible to account for all variation associated with each language, and a fortiori, for each language pairing. In the current study we examined a large number of language pairs (13 pairs) with British English common across all pairs. Our sample provides variation in terms of linguistic distance and cultural background, as a subsample of all possible pairings. These data were analysed with linear mixed models which include a factor for random variation due to language community, but also linguistic distance as a “between-language” fixed factor. If linguistic distance has an effect then it can be used to usefully explain some of the variance in scores that would otherwise simply be apportioned to language community.

In sum, we discussed how linguistic distance between a bilingual’s two languages can be estimated on three dimensions: phonological overlap, subject-verb order typology and morphological complexity. We also reviewed how current views on the structure of the early bilingual language system can accommodate an effect of linguistic distance on vocabulary size. This was the rationale for our first study, to quantify the amount of variation due to linguistic distance in the development of vocabulary at age two. In what follows we discuss our second, applied aim, which was to build a model of the bilingual early lexicon able to account for the variance due to situational factors related to bilingual experience, linguistic distance and language community, providing norms of vocabulary development for assessment purposes (the UKBTAT).

Study 2: Providing Norms of Vocabulary Development for Bilingual Toddlers

It is well documented that bilinguals generally command a smaller vocabulary in each language than monolinguals (e.g., Bialystok, Luk, Peets, & Yang, 2010; Hoff et al., 2012; Miękisz et al., 2016; Oller & Eilers, 2002; Perani et al., 2003; Portocarrero, Burright, &
Donovick, 2007; Smithson, Paradis, & Nicoladis, 2014). This fact is critical for assessing children’s language development because vocabulary size is a central measure of progress in both the oral and literate forms of language (Muter, Hulme, Snowling, & Stevenson, 2004). Indeed, vocabulary size correlates highly with grammatical development (Conboy & Thal, 2006; Hoff, Quinn, & Giguere, 2017; Thal, Bates, Goodman, & Jahn-Samilo, 1997), and is strongly predictive of later language impairment (Conti-Ramsden & Botting, 1999; Dale, Price, Bishop, & Plomin, 2003) and reading comprehension skills (Duff, Reen, Plunkett, & Nation, 2015), making it a reasonable proxy of language development achievements in young toddlers (see also Cattani et al., 2014).

Getting an accurate estimate of the “bilingual difference” in vocabulary size for each language is a prerequisite to adapting existing assessment tools for the evaluation of bilingual toddlers’ language achievements. Furthermore, language disorders occur with similar prevalence in both the monolingual and bilingual populations (Kohnert, 2010), with all children having a 7-15% chance of experiencing delayed language acquisition due, for example, to pervasive developmental disorders such as autism (e.g., 2.6%, Kim et al., 2011), hearing impairment (e.g., 1% in Fortnum et al., 2001) or Developmental Language Disorder (e.g., 7%, Tomblin et al., 1997). Current language assessment methods are based upon expectations for monolingual learners, and take no account of comparative delays seen in typical bilingual lexical development (Gathercole, 2007) or grammar (Bedore & Peña, 2008; Bialystok, 2009; Kohnert, 2010). Thus, according to circumstances, bilinguals, who are in reality typically-developing, may be diagnosed with spurious acquisition problems or have genuine problems ignored (e.g., Crutchley, 2000; Salameh, Nettelbladt, Håkansson, & Gullberg, 2002, for evidence of under-referral in bilingual children). Moreover, whilst recommendations to practitioners are that proficiency in both languages should be assessed (American Speech-Language-Hearing Association, 1999; Royal College of Speech and
Language Therapists, 2007), this is in practice complicated by the diversity of language pairs (Cattani et al., 2014; Thordardottir, Rothenberg, Rivard, & Naves, 2006).

An approach advocated by Pearson, Fernandez and Oller (1993) for Spanish-English and Junker and Stockman (2002) for German-English bilinguals is to obtain for each child her total vocabulary in the two languages, either by counting all tokens (Total Vocabulary or TV; e.g., dog and its French equivalent chien would count as one entry each) or counting two known translation equivalents as one (Total Conceptual Vocabulary or TCV; e.g., dog and chien would count as one entry). Based on findings that bilingual children score similar to monolinguals when using their TV or TCV measures, it was proposed that bilingual norms might not be necessary, as long as vocabulary could be estimated in both languages. However, Thordardottir et al. (2006) reported that the use of TCV/TV measures was not appropriate for balanced bilinguals, that is, those hearing equal amounts of each language on a regular basis, or children whose language dominance is not clear. They attributed this to the large overlap in knowledge from their two languages, which would modulate the relationship between measures using one language (monolingual norms) or two languages (TV/TCV). In addition and most importantly, they found that the comparison of TCV/TV to monolingual norms was highly dependent on which monolingual group is used for comparison, as vocabulary growth can vary substantially between languages (Thordardottir, 2005), for example when presented with a particularly complex vowel system as in Danish (Bleses et al., 2008). Core, Hoff, Rumiche and Señor (2013) also found that between 22 and 30 months, TCV scores placed significantly more bilinguals below the 25th percentile on monolingual norms than single-language scores did for monolinguals (see also Gross, Buac, & Kaushanskaya, 2014).

Therefore, measuring bilingual vocabulary appears to be an impractical task given the variety of factors that might shape lexical growth in these children, from the variation between language pairs to situational factors such as amount and mode of exposure (e.g.,
Hoff et al., 2012; Place & Hoff, 2011). The aim of our second study was to provide a new functional approach to the evaluation of vocabulary knowledge in bilingual children, addressing the diversity of bilingual children’s situations, in particular, variation in the linguistic distance between each bilingual child’s two languages. To our knowledge, this is the first time that data were collected from a large cohort of bilingual children learning a variety of language pairs, in an attempt to capture empirically the effect of language community and linguistic distance on other factors known to modulate vocabulary growth in bilingual children. In addition, by focusing on children who share one language (here, British English), we avoid having to rely on different standardised tools that may vary dramatically across languages (Thordardottir, 2005). Whilst the resulting norms of vocabulary growth are specific to children learning British English as one of their languages, our rationale and methods are, we believe, generalisable to any new population of bilingual toddlers.

**Assessing language development: The case of the UK.** In the historical context of the British Empire and more recent European Union expansion, the UK bilingual population is characterised by a great diversity of language backgrounds, with no predominant group such as Spanish-English in the US (with the exception of Welsh in North Wales). As such, it can be taken as a representative case study for the widespread situation where the professionals who assess young children have no easy access to an appropriate standardised monolingual assessment tool, let alone a bilingual tool. In what follows we will review briefly the current practices of screening and assessment of bilingual children in the UK.

Recently, the Dynamic Assessment of Preschoolers’ Proficiency in Learning English (DAPPLE) was developed in the UK to respond to the clinical need to distinguish between a disorder and the bilingual difference, using a mixed group of bilinguals, that is, children learning English and a variety of Additional Languages (Hasson, Camilleri, Jones, Smith, & Dodd, 2013). This assessment examines the children’s ability to learn vocabulary, sentence
structure and phonology. This battery of language skills assessments sounds promising as a pre-diagnostic tool but is designed for children aged 42 months; in addition, it has been criticised for issues regarding inter-rater reliability (Hasson & Joffe, 2007) and is usually very time-consuming (De Lamo White & Jin, 2011).

Since 2013 the professionals who assess young children use general developmental questionnaires at age 2 which include language components, such as the revised Ages and Stages Questionnaires (ASQ: Squires & Bricker, 2009). However, each of these tools is designed and normed for monolingual development which, along with the lack of adequate language assessment tools for that age range, means that bilingual 24-month-olds continue to be at risk of under-referral (Crutchley, 2000; Salameh et al., 2002).

The linguistic heterogeneity of the UK regarding its bilingual population, and the clear clinical need, motivated the second and third studies reported in this paper: from the estimation of the impact of language community and linguistic distance on bilingual lexical development obtained in Study 1, we developed a full model of the bilingual lexicon at age 2 which provided norms of development, the UKBTAT (Study 2), and showed that it could be used for bilingual toddlers learning British English and a new Additional Language not included in the original target set (Study 3). The UKBTAT, designed to address issues faced by childhood professionals in a range of bilingual situations, has the following characteristics: (1) it is targeted for 24-month old children, a milestone age easy to remember for parents and practitioners, and relevant for the UK policy of assessing children from this age; (2) it is usable for any child learning British English and any other Additional Language from our 13 target languages – and can also provide useful information regarding English development for children learning another Additional Language; (3) it is user-friendly and easy to administer, relying on short parental questionnaires about the child’s vocabulary knowledge, and a 10-minute interview with the parent/carer (which can be done on the phone) to collect
critical data on language exposure and demographics; (4) it provides interpretable results even if parents or carers estimate their child’s knowledge of English only, although the added information about the Additional Language, when available, enriches the outcome; and (5) it can be used by a non-language-specialist practitioner, it is freely accessible online on a dedicated website and easily printable if needed.

From the cohort of toddlers tested in this project, we collected detailed information about family composition and characteristics, and level/mode of exposure to English and the Additional Languages. Many studies have examined situational factors that could impact the rate of language development in bilingual children, including socio-economic status (e.g., Calvo & Bialystok, 2014; Gross et al., 2014), relative amount of exposure to each language (e.g., Hoff et al., 2014), mode of exposure, such as number of speakers per language (e.g., Gollan, Starr & Ferreira, 2015), daycare attendance (e.g., Hansen & Hawkes, 2009), or language mixing (e.g., Byers-Heinlein, 2013). Such studies typically focus on no more than three factors at a time, making it difficult to quantify the relative contributions and interactions of all factors on a single measure of language achievement. A recent exception is the 250-children study by O’Toole et al. (2017), who compared vocabulary in six groups of bilingual children aged 24 to 36 months growing up in different countries (Maltese-English, Polish-English, French-Portuguese, Hebrew-English, Irish-English, Turkish-German) using adaptations of CDIs, and examining the contribution of a range of situational factors to TCV measures. They reported some large, unexplained variations in TCV measures across language groups, possibly due to linguistic distance, with for example Maltese-English and Polish-English groups scoring lower than the other groups. However because they tested children from a range of linguistic, cultural and geographical backgrounds, it is impossible to disentangle variance due to any of these factors from that due to linguistic distance.
The current study is the first extensive study of the effects and interactions of the potentially critical factors for language development in bilingual toddlers learning one common language: relative exposure to the two languages, family demographics, mode of exposure (which uncovers a range of factors, as described below) and, innovatively, language community (i.e., the specific Additional Language being spoken) and linguistic distance between English and the Additional Language. Quantifying the contributions of these factors to the trajectory of vocabulary development in bilingual toddlers will be critical to provide an accurate picture of expected language outcomes at 2 years. In what follows we review the potential factors that influence vocabulary knowledge at age 2 in bilingual toddlers.

**Relative amount of exposure to languages.** It is firmly established that the relative exposure to each language strongly influences bilingual children’s rate of development in those languages (Welsh: Gathercole & Thomas, 2009; Spanish: Hoff et al., 2012; Pearson, Fernandez, Lewedeg, & Oller, 1997; French: Thordardottir, 2011; Cantonese and Mandarin: Law & So, 2006); indeed, relative exposure has been advocated as a proxy for language dominance (Unsworth, 2012). Relative exposure predicts development of phonology (Law & So, 2006), lexicon (Cattani et al., 2014) and grammar (Gathercole, 2002a; 2002b; 2002c; Nicholls, Eadie, & Reilly, 2011; Oller & Eilers, 2002). How to measure the exposure to each language varies from one study to the next or from one lab to the next, for example asking parents to use a prospective language diary (e.g., De Houwer & Bornstein, 2003; Place & Hoff, 2011), or using a detailed questionnaire or interview about regular exposure to each language (e.g., ALEQ: Paradis, 2011; Language Exposure Questionnaire: Bosch & Sebastián-Gallés, 1997; Thordardottir, 2011; Hoff et al., 2012). Because these questionnaires tend to be long and complex to administer, we developed our own Plymouth Language Exposure Questionnaire tool (Cattani et al., 2014), consisting of a 5 to 10 min interview with the parent (face-to-face or on the phone), comprising 10 to 12 simple questions about a child’s typical
week. In a group of 35 mixed bilinguals aged 30 months, Cattani et al. (2014) showed that the amount of exposure as measured by the Plymouth Language Exposure Questionnaire predicted vocabulary scores in comprehension and production as measured by the Oxford CDI (Hamilton, Plunkett, & Schafer, 2000): specifically, the more exposure to English (relative to the Additional Language) children experienced in a typical week, the more words they understood and used in English. Recently, Abdelwahab, Stone, Slee, Cattani and Floccia (2016) also showed a strong correlation between scores from the Plymouth Language Exposure Questionnaire and three other widely-used questionnaires (ALEQ: Paradis, 2011; MLEQ: Yang, Blume, & Lust, 2006; Language Exposure Questionnaire by Bosch & Sebastián-Gallés, 1997), with correlations ranging from .62 to .79.

The Plymouth Language Exposure Questionnaire primarily collects information about speech directed towards children, as the consensus is that children’s language development benefits from joint attention situations (e.g., Tomasello & Farrar, 1986) and infant directed speech (Weisleder & Fernald, 2013). However, in many cultures children are not directly addressed (Lieven, 1994), and recent studies have showed that word learning at 18 months, for example, can be elicited from overheard speech (Floor & Akhtar, 2006). Furthermore, bilingual infants as young as 3.5 months benefit from overheard speech in their ability to discriminate between their two native language(s) (Molnar, Gervain, & Carreiras, 2014). In fact, in many tools used to quantify the relative amount of exposure to each language, both direct (speech to the child) and indirect (speech between adults) sources are taken into account in the calculations (e.g., Paradis, 2011; Yang et al., 2006). To complement the Plymouth Language Exposure Questionnaire measure and ensure that we quantify all possible sources of English/Additional Language input, the proportion of British English versus Additional Language used in overheard speech between parents was also evaluated in the current study.
**Mode of exposure.** Mode of exposure is probably the most complex factor to estimate, as it includes a range of variables such as the *source* of each language (e.g., presence of siblings, number of speakers per language, social context of exposure, e.g., crèche versus home), the *status* of the languages in the environment (minority language, such as Mandarin in a Plymouth family, or predominant cultural bilingualism as Welsh and British English in Bangor), and the *properties* of the input (language mixing; native versus non-native input). It is a current matter of debate whether these variables have a significant effect on bilingual language development, especially in toddlers.

**Source of each language.** The bilingual child’s relative proficiency between languages appears to be modulated by the source of exposure, that is, who is speaking to them in each language. For example, Barrena, Ezeizabarrena and Garcia (2008) reported that Basque-Spanish young bilinguals knew more words in the Additional Language (Basque) when both parents were Additional Language speakers as compared to when only one was an Additional Language speaker - although this factor could be confounded with the amount of exposure in this study. It is also possible that there may also be differences depending on *which* parent is the source of Additional Language (please note that at this stage, the wording in the various questionnaires follows the heterosexual family model). Fathers generally direct less verbal output to their children than mothers, as they spend a greater proportion of their time interacting through play activities, especially physical play, which reduces the density of their speech (e.g., Pancsofar & Vernon-Feagans, 2006).

More generally, the effect of the number of speakers per language has recently been studied (e.g., Gollan et al., 2015), given theoretical proposals that variability in speech input supports the construction of phonological categories in early infancy (e.g., Rost & McMurray, 2009; Singh, 2008). Place and Hoff (2011) report that 25-month-olds Spanish-English bilinguals knew more words in English if they interacted with a larger number of speakers in
that language, once corrected for the overall amount of exposure to English (see also Gollan et al., 2015). However, this finding was only partially replicated in Place and Hoff (2016) with a larger sample of 90 30-month-olds learning Spanish and English, where modest speaker number effects were found, predictive of knowledge in Spanish only. In the current study, we therefore examined the effect of vocabulary scores on the number of speakers per input language.

The impact of daycare attendance on children’s development is a longstanding question in child development research, with mixed data (e.g., Brooks-Gunn, Han & Waldfogel, 2002; Ruhm, 2004). One of the few consistent overall results is that daycare attendance tends to benefit children from low SES. For example, using data from about 13,000 children in the British Millennium cohort, Côté, Doyle, Petitclerc and Timmins (2013) report a cognitive advantage at age 3 for children who have attended daycare, but only for those from low SES, and only below age 5. However, Hansen and Hawkes (2009), using the same cohort data, show that vocabulary outcomes are not significantly affected by daycare, with the exception of grandparent care which benefit mainly children from higher SES families. We measured how vocabulary outcomes are modulated by daycare attendance and language spoken within that environment.

The presence of older siblings is another potential source of variation. In monolingual homes, first-born children tend to acquire language faster than later born siblings (e.g., Fenson et al., 1994, 2007, for production; Huttenlocher, Haight, Bryk, Seltzer, & Lyons, 2010), presumably because they get more joint attention opportunities with adults and because child-directed speech produced by adults is of better quality than that produced by children. For bilingual children, this should result in a larger vocabulary in both languages for first-borns than later children. However, Bridges and Hoff (2014) found that North American bilingual toddlers with older siblings were more proficient in English compared to other
bilingual children with no older siblings, presumably because older bilingual siblings were more likely to use English when addressing toddlers than other members of the family. Therefore, although input from older siblings may contain more ungrammatical structures and less diverse vocabulary, it nonetheless tends to contain a higher proportion of English, thus leading to higher levels of English vocabulary in the target children. Based on these findings we examined whether the number of older siblings at home had any effect on vocabulary development and especially English production skills.

**Properties of the input.** We use “properties of input” to refer to whether children interact with speakers who are consistent in their language use, and whether or not the input is produced by a native speaker. Within-speaker consistency can be measured as the degree of code-switching or language mixing (i.e., including elements of each language at the sentence level), which is estimated to occur significantly often for many bilingual children (e.g., over 20% in Marathi-English bilinguals: Tare & Gelman, 2011; between 2 and 10% in Brazilian-Portuguese English bilinguals: Nicoladis & Secco, 2000). It can also be measured more broadly as the adherence to the one-parent-one-language principle, that is, the extent to which children hear the two languages from the same person. Within-speaker inconsistency is potentially seen as a delaying factor in language development (especially code-switching at the sentence level), as language acquisition theorists usually argue that language separation early in development should optimise learning mechanisms (e.g., Curtin, Byers-Heinlein, & Werker, 2011). Indeed, Byers-Heinlein (2013) found that intra-sentential code-switching was detrimental at 18 months, although only marginally at 24 months. Evidence for the importance of the one-parent-one-language principle is less straightforward (e.g., de Houwer, 2007). Place and Hoff (2016) tested ninety 30-month-old Spanish-English bilingual children (see also Place & Hoff, 2011), and after controlling for gender, maternal education, and the child’s relative language exposure, they reported no robust relations between the frequency of
mothers’ use of the two languages (measured at the discourse level, not within sentences) and measures of their children’s English or Spanish skills. They concluded that the negative effect of the adherence to the one-parent-one-language principle may be minimal on children’s language development or perhaps influential only at the very early stages of language development. Here we assessed the effect of consistency of parental language use on our target population of bilinguals. One possibility, which we examined here, is that the negative impact of parental code-switching on vocabulary development (Byers-Heinlein, 2013) might be mainly found for pairs of languages with a minimal phonological overlap, as Byers-Heinlein primarily examined distant language learners whereas Place and Hoff (2016) – who used the broader measure of adherence to the one-parent-one-language principle - looked at close language learners. The rationale behind this hypothesis is that frequent switches between distant languages would require a greater flexibility (and therefore cognitive resources) to navigate from one set of representations over another, as compared to close languages which activate overlapping representations.

Another qualitative aspect of the input that might modulate bilingual children’s vocabulary growth, is the nativeness of the adult speaker in each language. The hypothesis that native speakers provide more supportive input in their language than non-native speakers is a matter of controversy. Fernald (2006) suggested that being presented with both native and non-native speech in their two languages could lead infants to have more difficulties in discriminating between them, and subsequently impair development of phonological categories (young bilinguals do learn some phonological contrasts later than monolinguals: Bosch & Sebastián-Gallés, 2003; Burns, Werker, & McVie, 2003). It could be also that non-native speakers tend to use less varied vocabulary (Hoff, Coard, & Señor, 2013). However, Paradis (2011) examined 4- to 7-year-old immigrant children in Canada and found that mothers’ proficiency in English was not a significant predictor of children’s English
vocabulary - although children’s exposure to native speakers through media or friends was a predictor. In contrast, Hammer et al. (2012) reported that for Spanish-English 59-month-old bilinguals, English proficiency of mothers was a fair predictor of their children’s scores in English tests, although they did not control for the relative exposure to English/Spanish. Place and Hoff (2011) reported that in 29 Spanish-English bilinguals aged 25 months, English vocabulary was positively correlated with the amount of English produced by native as opposed to non-native speakers, controlling for overall exposure. More recently, Place and Hoff (2016), with a larger sample of 90 30-month-old Spanish-English bilinguals, also reported a small but positive influence of the proportion of native-speaker input on English knowledge when measured with standardised tests (PLS-4: Zimmerman, Steiner & Pond, 2002; EOWPVT: Brownell, 2001). They found no effect on CDI measures, however. Based on these findings, we examined if the proportion of parental native versus non-native speech has an effect on children’s vocabulary size in each language.

**Status of the Additional Language.** Whether children grow up bilingual in a monolingual or bilingual society may have consequences for their degree of achievement in both languages. Bilingual children from minority populations such as recent immigrants (e.g., Cantonese/English speakers in the UK) tend to have lower academic outcomes in mainstream education than monolinguals (Prevoo Malda, Mesman, & van IJzendoorn, 2016), likely driven by poorer English reading comprehension skills. This disadvantage is particularly acute if English is not their dominant language (Strand, Malmberg, & Hall, 2015). In contrast, when bilingualism is the norm within a particular society, such as in certain Welsh communities, the cognitive and academic achievements of bilingual children can be equal (Rhys & Thomas, 2013) or even better (i Trueta, Barrachina, & Pascual, 2012) than their monolingual peers. Thus, in a bilingual society children’s achievements in both their languages might be advantaged, as compared to children learning English and an Additional
Language in a monolingual community. We explicitly tested this hypothesis through the inclusion of a target cohort of Welsh-English toddlers selected from a bilingual community in North Wales.

**Demographic factors (SES and gender).** Monolingual children from lower socio-economic groups tend to have poorer language skills than those from higher SES (Deutsch, 1965; Hoff-Ginsberg, 1998; Rack, Snowling, & Olson, 1992), perhaps because of the characteristics of maternal input (Hoff, 2003) and/or the home attitude towards literacy (Payne, Whitehurst, & Angell, 1994), which includes low frequency of shared reading activities at home (Britto, Fuligni, & Brooks-Gunn, 2002; see Tomalski et al., 2013, for showing that SES shapes brain activity in early infancy). Unsurprisingly, this SES related language advantage also extends to bilingual children (e.g., Calvo & Bialystok, 2014; Gathercole, Kennedy, & Thomas, 2016; Ollers & Eilers, 2002; Paradis, 2009). It has similarly been proposed that this effect is partially due to the higher quality of language provided by mothers with a high education background, improving their children’s acquisition of the maternal language, and transferring to an advantage in the Additional Language even if the mother does not use it (Goldberg, Prause, Lucas-Thompson, & Himsel., 2008; Paradis, 2009).

It is important to note however, that in monolingual toddlers the effect of SES on vocabulary size as measured by CDIs is heavily dependent on the presence of children from very low SES backgrounds in the sample. Where such children are not systematically recruited there are negligible or null effects: for example, in the latest cohort tested with the MacArthur CDI (Fenson et al., 2007; N = 2007), no effect of SES (as measured by maternal education) was found between 13 and 20 months, and significant but very small effects were reported in production from the age of 21 months onwards. The original MacArthur CDI cohort (Fenson et al., 1994; N = 1130) found a very small correlation between SES and
vocabulary production in 16-30 months old toddlers ($r = .05$). Similarly, in the Oxford CDI, Hamilton et al. (2000) did not find any correlation between SES and vocabulary scores in production or comprehension. In contrast, the studies of Fernald, Marchman and Weisleder (2013) and Arriaga, Fenson, Cronan and Pethick (1998), which sampled extensively from low SES families, demonstrated significant if modest SES effects.

This pattern of findings suggests that the effect of SES may be limited to the lower thresholds of SES indexing. Note that this is not to be necessarily expected from other measures of vocabulary, such as naturalistic recordings as used by Hoff (2003), who found differences between mid and high-SES children.

Gender is also a well-documented factor in vocabulary growth, with girls usually producing more words than boys (Huttenlocher et al., 1991), without necessarily showing better comprehension scores than boys (girl advantage in Fenson et al., 2007; equal levels in Eriksson et al., 2012). In the original MacArthur CDI cohort of 8- to 30-month-olds (Fenson et al., 1994), gender was found to account overall for 1 to 2% of the variance, and more in production than comprehension. This production advantage for girls was found to be consistent across linguistic communities as demonstrated with CDI data collected from 10 large non-English groups (Eriksson et al., 2012), pointing to a common neurophysiological explanation rather than sociological/cultural causes - or perhaps to widely shared conventions of encouraging more communication with girls.

To summarise, we have reviewed the situational factors which might shape vocabulary knowledge in bilingual toddlers: relative amount of exposure, mode of exposure (an umbrella term for a range of factors related to the source of the Additional Language, the properties of the input, and the Additional Language status), and demographics. These factors, together with language community and metrics of linguistic distance, were used to build a model of the bilingual lexicon at age 2 for assessment purposes, the UKBTAT (Study 2). In
what follows, we discuss the rationale and objectives of the third study, which was to extend
this model to bilingual toddlers speaking British English and any Additional Language
different from those used to generate the lexical model in Study 2.

**Study 3: Generalising Language Assessment to any UK-Raised Bilingual**

As mentioned above, professional bodies such as the Royal College of Speech and
Language Therapists recommend that bilinguals should be assessed in their two languages, as
the variety of factors modulating bilingual development prevents a direct comparison of their
achievements with corresponding monolingual norms (Kohnert, 2010). Our aim in Study 2
was to accommodate these factors to provide norms of development in English and 13 target
Additional Languages and create the UKBTAT assessment tool; in Study 3 we aimed at
establishing whether the estimates of English vocabulary generated for the UKBTAT would
allow identification of possible language delays for any incoming non-target Additional
Language (avoiding the requirement for normed data on all possible language pairs, which is
practically impossible).

The possibility of an English-only screening tool is based on two theoretical premises.
First, in bilinguals, Developmental Language Disorder, as well as language-based learning
disabilities, affect both languages (Håkansson, Salameh, & Nettelbladt, 2003), insofar as such
disorders are underpinned by a genotype affecting neurological functioning (e. g. Leonard,
1987; Schwarz, 2010). Therefore, any domain of impairment, for example morphosyntax –
the most documented so far (e. g. Rice, 2004) – will be observable in the two languages.
However, due to relative delays in growing the two languages, and to the language-specificity
of the complexity of morphological rules, difficulties in language learning could appear more
severe in one language as compared to the other. But our point remains that a delay or a
difficulty is expected in both languages, when compared to norms of development.
The second premise is that, although not all late talkers in early childhood are going to develop a primary language impairment (e.g., Rescorla, 2005), almost all children diagnosed with DLD later in childhood had a history of initial language delay, in the form of protracted vocabulary development in comprehension and production (Conti-Ramsden et al., 1997). Hence, Dale et al. (2003) reported that monolingual 2-year-olds who scored below the 10th percentile on the MacArthur–Bates Short Form CDI in production were significantly more likely to be diagnosed as DLD when reaching the age of 3 to 4 years. Out of the 6,500 children who scored above the 10th percentile for vocabulary production at 2 years, only a tiny fraction exhibited grammatical difficulties one or two years later. Early receptive language difficulties have an even higher predictive validity of later language disorder diagnosis (e.g., Beitchman et al., 1994; Chiat & Roy, 2008).

The corollary of these two premises is as follows: if we could detect the late bilingual talkers at age 2 years in English only, when all other sources of variation have been factored in, we would have identified the main cohort from whom language impaired children will be diagnosed one or two years later. While we agree that collecting information about a bilingual child’s language development in both languages is still relevant and informative for clinical and research purposes, practitioners or researchers might not always be familiar with both languages. Thus the ability to work with only one of the two languages of a bilingual is important from a theoretical as well as a practical point of view.

In order to achieve this goal, we examined whether the model of the bilingual lexicon generated in Study 2 using a sample of 13 target bilingual groups could reliably predict the English scores of a new sample of children learning British English and a non-target Additional Language.

**Summary of Research Questions and Key Predictions**
We analysed vocabulary data, situational factors, linguistic distance and language community in a sample of two-year-olds learning British English plus either one of 13 target Additional Languages (N = 372) or one non-target Additional Language (N = 58). Three studies were performed with the same data set: investigating the effect of linguistic distance on vocabulary development (Study 1, just using the target Additional Languages), building a model of the bilingual lexicon at age 2 using a range of situational variables and linguistic distance for the target Additional Languages learners, resulting in the UKBTAT (Study 2), and testing its generalisability for the non-target learners (Study 3). To fulfil the objectives of Study 1 and estimate the impact of linguistic distance on vocabulary development, it was necessary to first get a full estimate of the effects of all situational factors that were known or suspected to shape bilingual development. The following predictions were formulated:

- Given the solid evidence of the importance of the amount of language exposure in expressive and receptive vocabulary growth (e.g., Hoff, 2003), we expected this factor to be a robust predictor of vocabulary knowledge. In particular, we predicted that children with more exposure to English would have higher scores in both receptive and expressive vocabulary scores in English - and conversely, lower vocabulary scores in the Additional Language. We predicted that these effects would be strongest in our measure of direct exposure, obtained through the Plymouth Language Exposure Questionnaire, but might also be found in our measure of indirect exposure via overheard conversation between parents (referred to as Overheard speech).

- We predicted an effect of gender, with girls outperforming boys (Eriksson et al. 2012), especially in expressive vocabulary (Fenson et al., 2007).

- SES was expected to modulate language outcomes, with smaller expressive and receptive vocabularies for children from lower SES families (Gathercole et al., 2016).
Regarding the effect of those factors related to the mode of exposure to each language (source, properties and status), one objective of this first study was to assess whether effects described in the literature for specific English-Additional Language pairings are robust over a range of languages.

The effect of language community was an unknown variable, and was expected to generate a large amount of unexplained variance, due to a variety of cultural and linguistic factors. We hypothesised that part of the variance attributed to language community could be accounted for by linguistic distance between British English and the Additional Language, as measured by the phonological overlap between translation equivalents, the word order typology and morphological complexity.

Study 2 did not generate predictions per se, as its objectives were to build an assessment tool based on findings from Study 1. However, for Study 3, we predicted the following:

In our models of vocabulary developed in Studies 1 and 2, Language Community was treated as a random factor to acknowledge that our 13 target languages comprise a non-exhaustive sampling of possible language pairs. The success with which the random effects modelling could produce a model that generalises beyond these target languages was assessed by establishing how well our models could generalise to a test set of 58 children whose Additional Language was not part of our 13 target languages, and therefore not represented in the model.
Chapter 2 - Methods

The methods described in this chapter cover the cohort data collection, which constituted the common data set for all three studies reported in this paper. A sample of 430 bilingual toddlers, learning British English and one of 13 target Additional Languages (N = 372), or any other Additional Language (N = 58), were identified over a 2-year period. To increase variation in both English/Additional Language pairs and in the situational factors outlined above (language exposure, mode of exposure and demographic factors), data was collected through trained research assistants recruited in the six universities involved in this project (Bangor, Birmingham, Kent, Liverpool, Oxford and Plymouth), as well as in Bristol and Leicester, each having access to multilingual populations to various degrees. However, since the testing platform was remotely accessible, the final sample comprised families from all areas of the UK, apart from Scotland and Northern Ireland. Bangor had the additional advantage of being located in a region with 75% bilingual Welsh-English children, providing a unique opportunity to compare language skills in bilinguals growing in a region with predominant bilingualism, to those whose bilingualism is linked to immigration.

When the child approached her second birthday, volunteer parents were contacted via the website UKBilingualToddlers, and the following data were collected in this order: English expressive and receptive vocabulary as measured through a bespoke Oxford Short Form CDI (Hamilton et al., 2000); Additional Language vocabulary as measured through the corresponding version of the CDI, when available; a family questionnaire with detailed questions about demographics (developed for the UK-CDI standardisation project, Alcock et al., in prep); and the Plymouth Language Exposure Questionnaire (Cattani et al., 2014) which provided the LEQ measure of relative exposure to each language.
To sum up, the current study measured four parent-assessed outcome variables at 24 months: receptive English vocabulary, expressive English vocabulary, receptive Additional Language vocabulary and expressive Additional Language vocabulary (through CDIs). For each of these outcome variables, we investigated the influence of the following factors: 1) gender, 2) SES (as assessed via parental income and educational level), 3) proportion of child-directed speech in English (LEQ), 4) proportion of overheard parental speech in English, 5) factors related to the source of each language (whether two parents were native Additional Language speakers or only one, number of sources of English, number of sources of the Additional Language, time in daycare in each language, number of older siblings), 6) factors related to the properties of the input (degree of language use consistency in parents’ input, number of native and non-native speakers in each language), 7) status of the Additional Language (societal vs. minority), 8) the particular language community (i.e. which of the 13 additional languages the child was exposed to) and 9) the linguistic distance between English and the Additional Language as measured by a) phonological distance, b) morphological distance and c) syntactic distance (see Table 1 for a summary of these variables).

Method

Participants. Data were collected for a total of 430 children between February 2014 and July 2016. The data of an additional 31 children were discarded as they had hearing problems (N = 7), had a diagnosed developmental delay (as reported by parents; N = 6), were too young or too old (N = 17), or had incomplete records (N = 1). The data of another 41 children could not be included as parents did not complete the study. Out of the remaining
final sample of 430 children (aged 23.89 months, SD 0.39, from 23.0 to 25.0; 193 girls and 237 boys), 372 were learning English and one of the 13 target Additional Languages: Bengali, Cantonese, Dutch, French, German, Greek, Hindi/Urdu, Italian, Mandarin, Polish, Portuguese, Spanish, and Welsh. Following King (2001), spoken Hindi and Urdu were classified as two varieties of the same language. The remaining 58 were learning English and one non-target Additional Language (see Table 2). The proportion of children born in the UK was 94.1% for the 372 children learning a target Additional Language, and 93.1% for the 58 non-target Additional Language learners. Out of these 430 children, the information for family income (an optional field) was not supplied for 15 children (13 in the target language community and 2 in the non-target language community). See Table 2 for a full description of the sample.

Procedure and instruments. The data collection was initiated when the children reached 23.5 months old. When signing the online consent form on the UKBT database, parents were notified that there were four tasks to complete for the study: none of these tasks involved testing the children, allowing for remote data collection. Specifically, the CDIs and the family questionnaire were completed on the online platform by the parents, and the Plymouth Language Exposure Questionnaire was completed by the research assistants during a final telephone interview. A paper copy of the questionnaires was sent to parents who were unable to access the internet. For some families who did not feel confident in English, the research assistants met with the parent(s) to help them go through the various questionnaires. When signing up, contact information and identification of the language(s) being spoken at home triggered the selection of the appropriate Additional Language CDI when available.
**Metrics of linguistic distance.** To create a toddler-centric representation of language
distance, each of the 406 non-onomatopoeic words from the Oxford CDI (Hamilton et al.,
2000), as well as their translation equivalents across the 13 target Additional Languages,
were transcribed into broad phonological representations. These were produced by trained
phoneticians, each of whom was a native speaker of the language they were asked to
transcribe. Our metric of language distance was then calculated as the overlap between the
phonological representation of a word in British English and its translation equivalent in the
Additional Language. This overlap was based upon the Levenshtein distance, that is, the
minimal number of insertions, deletions and translations that are required to get from the
British English phonological representation to that of the Additional Language. To produce a
proportional measure of overlap this distance was subtracted from the length of the longest
phonological sequence in British English or Additional Language, and then divided by the
same number. This produces a measure of phonological overlap for each word, between 0 (no
overlap) and 1 (perfect cognate), that preserves sequence order and is proportional to the
length of the word.

\[
Overlap = \frac{\text{Max}(\text{BE length, AL length}) - \text{Levenshtein distance}}{\text{Max}(\text{BE length, AL length})}
\]

An example of a calculation for the British English word “lamp” and its Italian
translation equivalent “lampada” is shown below:

**BE** lamp /l.æ.m.p/ : Sequence length = 4

**Italian** lampada /l.a.m.p.a.d.a/ : Sequence length = 7

Levenshtein distance (l.æ.m.p, l.a.m.p.a.d.a) = 4 (1 translation + 3 insertions)

\[
Overlap = \frac{\text{Max}(4,7) - 4}{\text{Max}(4,7)} = 0.43
\]
The language level phonological overlap between British English and each of the 13 Additional Languages is shown in Table 1, calculated as the average overlap across all 406 words.

For the measure of word order typology, the Additional Language was assigned a 1 if it had a VO order like British English, a 2 if it had a mixed VO/OV order, and a 3 for a OV order (see Table 1). Finally, morphological complexity was assessed on a 3 point scale, with analytic/isolating languages (Mandarin, Cantonese) being ranked closer to English (value 1), followed by fusional languages such as French and German (value 2) and agglutinative languages such as Hindi/Urdu and Bengali (value 3) (see Table 3). To illustrate, in analytic Mandarin number is not marked on nouns, as in 天 yī tiān "one day", 三天 sān tiān (lit.) "three day". In fusional French, the verbal suffix relates to grammatical mood, tense, aspect, person and number, as in mangeais "ate" (indicative, past, imperfective, second person singular) and mangerions "would eat" (conditional, present, perfective, first person plural). In agglutinative Bengali, nominative case for the word "river" is nodi, and the accusative nodike.

INSERT TABLE 3

Collecting demographic data. Demographic data were collected through the family questionnaire developed by Alcock et al. (in prep). This contains questions regarding (i) the health and development of the child, (ii) the child’s family history, (iii) parental information (e.g., parents’ educational level, income and postcode), and (iv) childcare arrangements. Some of these questions were repeated in the Plymouth Language Exposure Questionnaire (see below), but we tolerated overlap in order to retain each questionnaire’s integrity. Following Arriaga et al. (1998), we focused on household income and educational levels.
when measuring SES, as typical indices of SES are highly correlated. Income was divided in
four bands (variable Income), and education was measured on a seven point band that
correspond to English qualification classifications, from no qualifications to a postgraduate
degree (variables MumEd and DadEd; see appendix 2). Education was chosen as it is
generally used as a proxy for SES (e.g., Bornstein, Hahn, Suwalsky, & Haynes, 2003; Fenson
et al., 2007), and it is usually a better predictor of language development than income (e.g.,
Hoff, 2003); in addition we estimated that in the case of immigrant families, educational level
might better reflect the child’s learning environment than mere economic circumstances. The
educational status of both parents was used since the correlation between these two predictors
was not large (r = .29).

As with the Fenson et al. (2007) and Hamilton et al. (2000) studies, the current study
had an under-representation of low SES children within our bilingual cohort. This may be
representative of SES distribution across the national population of bilingual children:
Dustmann and Frattini (2011), using a variety of large scale British and international sources
collected between 1993 and 2009, observed that immigrant populations in the UK tend to
leave the education system later and have higher wages than their native peers. It is also
likely that this under-representation stems from sampling, with low SES bilingual families
reluctant to take part in research, especially in cases when they are not confident in English.

*Evaluating amount of exposure to each language.* The Plymouth Language
Exposure Questionnaire (Cattani et al., 2014) was used to obtain the percentage of direct
language exposure received by the child in English and the Additional Language in a typical
week based on a unique 5 to 10 minute phone interview (variable LEQ). The questionnaire
(available at [http://www.psy.plymouth.ac.uk/leq/](http://www.psy.plymouth.ac.uk/leq/)) requested information about (i) the average
number of hours spent by the child in nursery/with achildminder in each language
environment (variables EngDaycare and ALDaycare); (ii) the language(s) spoken by each
parent at home and the relative frequency of use of the two languages (variables MumPropEng and DadPropEng, measured on a 5-point scale); (iii) the number of hours spent by the child alone with each parent; (iv) whether the parents spoke equally with their child when both parents present; and (v) the number of hours of the child’s sleep in a typical day (to evaluate the number of possible contact time during a week). The detail of these variables and calculations leading to the proportion of English vs the Additional Language in a typical week (variable LEQ) is found in appendix 3.

To obtain the proportion of English/Additional Language in overheard speech (variable referred to as Overheard speech), an added question (5-point scale) was inserted after the original Plymouth Language Exposure Questionnaire (see appendix 2). See Table 4 for a summary of the results per language group.

**INSERT TABLE 4 HERE**

**Evaluating the mode of exposure (source, properties and status).** Measures of the various factors underpinning the source of each language were derived from questions which were part of the initial sign-up sheet, the family questionnaire and the Plymouth Language Exposure Questionnaire (see Table 5). Straightforward measures based on individual questions were the identification of the type of family (binary score for two parents native Additional Language speakers or only one; variable FamLang), the number of hours per typical week in English or Additional Language daycare (EngDaycare and ALDaycare), and the number of older siblings living in the house (until the age of 18 years; variable Siblings). Regarding the number of speakers in each language, a score of 1 was given to each native speaker parent, each older sibling, and attendance to a form of daycare (variable SourcesEng and SourcesAL, with an observed range of 0 to 6; see appendix 2).
Regarding the properties of the input (see Table 6), the degree of language use consistency from each parent was obtained through the questions in the Plymouth Language Exposure Questionnaire asking parents to quantify on a 5-point scale their relative use of English and Additional Language. Specifically, a parent would obtain a 1 for always speaking Additional Language, 2 for usually speaking Additional Language, 3 for English and Additional Language half of the time, 4 for usually speaking English and 5 for always speaking English (variable MumPropEng and DadPropEng). Then the degree of consistency would be recoded as a minimum of 1 if the answer to the above was a 1 or a 5; a 2 if the answer to the above was a 2 or a 4; and a maximum of 3 if the answer to the above was a 3 (variables MumConsistency and DadConsistency, averaged as Consistency).

The proportion of native/non-native speech produced by parents was calculated from the same question, in conjunction with whether the parent was a native speaker of Additional Language or not. That is, the number of hours spent with each parent during a typical week was calculated as: 168 (number of hours in a week) - total sleeping time - hours in daycare - hours alone with the other parent (variable A). Then, each parent’s score on their respective PropEng variable (1 to 5) was re-expressed as a proportion from 0 to 1 (1 = 0, 2 = .25, 3 = .5, 4 = .75, 5 = 1) to obtain the proportion of English in their speech (variable B). The resulting amount of English in this parent’s input was obtained by multiplying A by B. If this parent was a British English native speaker, then AB would correspond to the amount of native input, and if the parent was an Additional Language native speaker, AB would be the amount of non-native input. The final proportion of native English input across both parents (the variable PropEngN), was obtained by dividing the total amount of native English by the sum
of native and non-native English. The proportion of native Additional Language input (the variable PropALN), was calculated with a similar logic (see appendix 2).

**INSERT TABLE 6 HERE**

Finally, regarding status of the Additional Language, Welsh-English children growing up in Wales were coded as societal bilinguals, all others not.

**Measuring vocabulary.** To measure children’s vocabulary achievements in English and in their Additional Language for the 13 target languages, we used Communicative Developmental Inventories in each language. For the English CDI, we developed a 100-word version of the existing Oxford CDI (Hamilton et al., 2000), referred to as the Oxford Short Form CDI, by selecting words from the original 416 words which would (1) be representative of the words known and produced by 24-month-old monolinguals in the original norms that cover the same range of frequencies, and (2) contain the same distribution of syntactic categories (nouns, verbs, pronouns, etc). We selected 10 words understood and produced by 100% of 2-year-old monolingual toddlers as provided by the Oxford CDI database, then 10 words understood and produced by 90% of the same children, etc. Then we adjusted these words to include a proportion of nouns, verbs and function words similar to those found in the Oxford CDI (see appendix 5 for the full list). To verify the validity of this Oxford Short Form CDI, the parents of 134 monolingual children from the Plymouth area (including 72 girls) aged 10 to 26 months (mean age 17.9 months) completed both the short and the long CDI within a week (mean number of days between completions: 4.3 days, SD 5.5). Their mean score on the long Oxford CDI was 160.2 words in comprehension (out of 416; SD 119.7) and 80.3 in production (SD 107.9); their mean score on the Oxford Short Form CDI was 43.5 words in comprehension (SD 28.0) and 23.0 in production (SD 28.2). Children’s
scores in the two CDIs were highly correlated in comprehension ($r = .95$, $p < .0001$) and in production ($r = .86$, $p < .0001$).

We also compared the scores directly for the 100 words that were present on both the long and the 100-word versions of the Oxford CDI: monolingual children’s parents reported higher scores on the Oxford Short Form CDI, both for comprehension ($t (133) = 5.71, p < .0001$, mean Oxford CDI score = 39.2%; mean Oxford Short Form CDI: 43.5%) and production ($t (133) = 5.40, p < .0001$, mean Oxford CDI score = 20.4%; mean Oxford Short Form CDI: 23.0%). This difference is likely due to a fatigue or attentional effect when having to fill in a CDI four times as long as the 100 word Oxford Short Form CDI. Across the two completions, parents reported the same outcome (known or unknown) for 85.8% of words in comprehension, and 92.6% in production. Correlations between the short and long CDIs for the 100 words were $r = .95$ and $r = .98$ for comprehension and production respectively ($p < .0001$), indicating excellent validity for the Oxford Short Form CDI.

For the Additional Languages, we used the adaptations of CDIs for 12 Additional Languages with the authors’ permission (see list in the appendix 1), selecting the form adapted for the age of 24 months when multiple versions were available. Additional Language CDIs had lengths varying from 654 words in Greek (Kati, personal communication) to 62 in Bengali (Hamadani et al., 2010; see appendix 1 for references of CDIs).

We developed a new CDI for Hindi/Urdu as none were available. For simplicity we treated these two languages as dialects of the same language using different graphemic systems, so we developed the same version, written in the two alphabets. Following the method by Kern (2007), after a translation of the Oxford CDI, two focus groups of native Urdu speakers agreed on a cultural adaptation of the word list. Native Hindi speakers were consulted to check its adaptation to Hindi.
All parents were first asked to complete the Oxford Short Form CDI, assessing receptive and productive vocabulary separately (for each word, they were to assess whether the word was understood but not produced, or produced). If they felt unable to do so because, for example, they never spoke English at home and therefore could not estimate their child’s English knowledge, a proficient English speaking caregiver would complete a printed version of the CDI (e.g., a childminder). Parents were asked to complete the appropriate Additional Language CDI within a week of the completion of the Oxford Short Form CDI.
Chapter 3 – Analyses and Results for Study 1: Estimating the Effect of Linguistic Distance on Vocabulary Development

To estimate the impact of linguistic distance on vocabulary development, which was the aim of Study 1, we needed to account for the effects of all situational factors that were known or suspected to shape bilingual development. This was achieved through a two-step analyses of the data from the 372 children whose Additional Language was one of our 13 target languages.

Plan of Analyses

In the first step, analyses were conducted on variables already established within the literature as strong predictors of vocabulary size (relative amount of exposure to each language in child-directed speech and overheard speech, gender and SES). Analyses were conducted initially in ANCOVAs (to include continuous variables such as LEQ) and then subjected to confirmation in linear mixed models, with variables entered as fixed effects predictors only if they reached significance in the ANCOVAs.

In the second step, analyses were then conducted on less well-established variables (factors relative to source, properties and status, and measures of linguistic distance), in models containing verified predictors from the initial stage. Again, ANCOVAs were followed by linear mixed models with the same logic as in the first step.

The reasons behind this two-step process extend beyond the aims of Study 1, as explained below. The effects from the ANCOVAs would hold for a population with the same breakdown of language communities as those in our sample (e.g., which was 17.4% German, 12.8% French etc.). The linear mixed models do not make that assumption and are thus strongly preferred if conclusions are to be generalised to all bilinguals. The purpose of the linear mixed models was indeed to provide the best possible test for the importance of
candidate predictor variables for bilinguals generally, not merely those whose Additional Language was one of those 13 used in this paper (and therefore preparing for Study 3). For this it was imperative that Language Community be modelled as a random, not a fixed effect, as the ANCOVAs would do.

In contrast, the value of the ANCOVAs is that they allow a straightforward test of the significance of simultaneously entered predictor variables, something that is problematic with linear mixed models due to a lack of consensus on how to compute the degrees of freedom for each predictor (Baayen, Davidson, & Bates, 2008). Our procedure was thus to perform a preliminary selection of significant predictors from ANCOVAs, subject to confirmation in linear mixed models, before finally being included in predictive models.

Following steps 1 and 2, predictive linear mixed models of expressive and receptive vocabulary for the UKBTAT tool (Study 2) were calculated with predictors retained only if their effect size in the ANCOVAs was larger than $\eta^2 = 0.02$ (Cohen, 1988), which is considered a threshold for small effects in ANOVAs and multiple regressions. These final models do not include measures of linguistic distance, since we aimed at developing norms which could be applied to any bilingual children learning British English, and measures of linguistic distance would not be available for Additional Languages that are not amongst our 13 target Additional Languages. Predictive models for the UKBTAT (Study 2) and the test of their generalisation beyond the 13 target Additional Languages (Study 3) are presented in Chapter 4.

**Predictor Variables**

Step 1 predictors were language exposure scores (LEQ and Overheard speech), Gender, and SES. Language Community (which Additional Language is spoken by the child) was included as a 13 level dummy variable simply to control for its effects. Step 2 predictors were the mode of exposure variables, and three Linguistic Distance variables. Mode of
exposure variables belonged to three categories: source of each language (whether two parents are native Additional Language speakers or only one, total number of English speakers, total number of Additional Language speakers, number of siblings, time spent in English speaking daycare, time spent in Additional Language speaking daycare), properties of the input (degree of language use consistency in parents’ speech, proportion of native English, proportion of native Additional Language), and status of the Additional Language (Welsh group vs. all other Additional Languages). Linguistic Distance variables were phonological overlap, word order typology and morphological complexity.

Test language, or TestLang (English/Additional Language), was included as a repeated measures factor to examine the differential impact of predictors on English and Additional Language. See Table 1 for a summary of these variables.

**Vocabulary Measures**

Dependent variables were CDI counts of receptive and expressive vocabulary in English and the Additional Language. We conducted analyses on two different versions of the CDIs. Our starting point was a 30 word CDI made up of those 30 words present in the Oxford Short Form CDI and all 13 Additional Language CDIs (see Table A5-1 in appendix 5). This 30-word CDI had the advantage of holding items constant across a child’s two test languages, thus controlling, amongst other things, for word frequency (although frequencies between translation equivalents differed, correlations were in the order of .8 over the 13 English-Additional Language pairings). The disadvantage of this approach is that, of the words common across all CDIs, a disproportionate number were high frequency words. This results in a ceiling effect with, for example, over a third of children scoring 100% on English comprehension. Our second CDI used the full 100 words of the Oxford Short Form and the full Additional Language CDI re-represented as a percentage, to accommodate the fact that the standardised CDIs varied considerably in length for each language. While these data
suffer from no ceiling effects and maximise the sampling of vocabulary, they are the least satisfactory in that there is no control of word frequency between all Additional Language CDIs, that is, obtaining a 40% score in the German CDI is not necessarily equivalent to a 40% in the Portuguese CDI. The main analyses reported here were performed on the 30-word CDI, with a specific section added for the data from the full CDIs. Given that the results were essentially similar when using the 30-word CDI or the full CDIs, please note that the final equations in the UKBTAT (Chapter 4) are calculated from the 100 words of the Oxford Short Form for English (for increasing representativeness of the model’s coefficients), and the 30 words for Additional Languages when relevant.

**Descriptive Statistics**

*Predictors.* Tables 2 to 6 presented summary data of all predictor variables broken down by Language Community. Because of the strong associations between Language Community and predictor variables, it was important to use models that included Language Community to avoid attributing to predictor variables the explanatory power that was actually simply due to variability over language communities.

*Vocabulary measures.* All data for vocabulary measures in English (for the full cohort) are reported in Table 7, and in Table 8 for each Additional Language (for the 372 target Additional Languages learners only). On the Oxford Short Form CDI, children understood on average 67.9 words and produced 41.2 words (variables CDI100Comp and CDI100Prod). On the Additional Language CDIs, which varied in length, children overall understood 54.9% of Additional Language words and produced 24.2% (PropALcomp and PropALprod). When restricting the analysis to the 30 words common to all CDIs, children understood on average 24.4 English words and produced 17.0 (variables CDI30comp and CDI30prod). For the target Additional Language, children understood on average 21.7 words and produced 11.2 (ALCDI30Comp and ALCDI30Prod), which was significantly less than in
English (comprehension: paired $t (371) = 6.25, p < .0001$; production $t (371) = 11.51, p < .0001$). As noted before, all main analyses provided below were run on the 30-word CDIs, with analyses on the full form CDIs provided in a specific section.

Of interest is the comparison of the bilingual scores to monolinguals. Based on the Oxford CDI database for 125 monolingual children aged 23.0 to 25.0, 24-month-olds understand 73.6% of the 416-word CDI (SD = 16.9) and produce 48.3% (SD = 25.8). To compare these scores to those of the Oxford Short Form CDI, we applied a correction ratio computed from the comparison between the long and short CDI described in the “Measuring vocabulary” section (see Methods). A score in the long CDI divided by 0.90 provides an equivalent score on the short CDI. That means that the 24-month-old monolinguals are estimated to understand 81.8% of words and produce 53.7% if assessed with the Oxford Short Form CDI. In contrast, the cohort of 430 bilinguals understood 67.9% of the Oxford Short Form CDI (SD = 25.0) and produced 41.2% (SD = 26.0), which is significantly less than the monolinguals (comprehension: $t (553) = 5.84, p = .0001$; production: $t (553) = 4.74, p = .0001$).

INSERT TABLE 7

INSERT TABLE 8

Results

Step 1 - Predictors firmly established in the literature. We looked at four predictors: LEQ (proportion of English in child-directed speech), Overheard speech (proportion of English spoken between parents), SES and Gender. Three indices (income, maternal education and paternal education) were initially selected as potential predictors for
SES, but due to high correlations between income and parental education, and because income had the widest observed range, the latter was selected. Results are very similar if parental education is used. Thus our step 1 ANCOVA consisted of the between-subjects predictors of LEQ, Overheard speech, Income and Gender, with the within-subjects predictor of TestLang (Additional Language/English). Language Community was included as a between-subjects factor, since we wished to ascertain in Study 3 (as aforementioned) the degree to which all other predictors are generalisable to bilingual 24-month-olds regardless of the particular Additional Language she or he is learning. Separate ANCOVAs were run for production and comprehension scores. All ANCOVAs used as dependent variables the 30-words CDIs (see Table 9 and 10 for full results in comprehension and production respectively).

For comprehension there was no main effect of LEQ, but an interaction of LEQ and TestLang ($F_{1,342} = 75.07, \ p < .001, \ \eta^2 = .18$). Analysis of the effect of LEQ on each test language separately revealed that it significantly reduced Additional Language scores ($F_{1,342} = 18.81, \ p < .001, \ \eta^2 = .05$) and increased English scores ($F_{1,342} = 21.46, \ p < .001, \ \eta^2 = .06$): the more child-directed English children heard, the more English they understood, and the less Additional Language they understood (see Figure 1). Overheard speech (the proportion of English vs the Additional Language spoken between the parents when the child was present) significantly increased comprehension scores overall ($F_{1,342} = 10.55, \ p = .001, \ \eta^2 = .03$), and showed an interaction with TestLang ($F_{1,342} = 38.72, \ p < .001, \ \eta^2 = .10$). Breaking down the
effect of Overheard speech for the two test languages, while no effect was seen for Additional Language ($F < 1$), a beneficial effect was seen for English ($F_{1,342} = 32.42, p < .001, \eta^2 = .09$). The more English spoken between the parents, the more beneficial effect on English comprehension (see Figure 2). A main effect of Income was found ($F_{1,342} = 11.97, p = .001, \eta^2 = .03$) and no interaction with TestLang. There was no main effect of Gender ($F_{1,342} = 1.39, p = .24$) or interaction with TestLang ($F_{1,342} = .05, p = .82$).

INSERT FIGURE 1 HERE

For production no main effect of LEQ was observed but again an interaction with TestLang was seen ($F_{1,342} = 91.58, p < .001, \eta^2 = .21$). As in comprehension, individual analyses on each of the test languages revealed a negative effect of LEQ on Additional Language scores ($F_{1,342} = 17.09, p < .001, \eta^2 = .05$) and a positive effect of LEQ on English scores ($F_{1,342} = 25.94, p < .001, \eta^2 = .07$) (see Figure 1). Overheard speech showed no main effect but did show an interaction with TestLang ($F_{1,342} = 34.08, p < .001, \eta^2 = .09$). Breaking down the effect for the two test languages showed a significant detrimental effect on Additional Language ($F_{1,342} = 3.91, p = .049, \eta^2 = .01$) and a beneficial effect on English ($F_{1,342} = 143.30, p < .001, \eta^2 = .04$) (see Figure 2).

INSERT FIGURE 2 HERE

Income did not have a significant effect ($F_{1,342} = 3.39, p = .07$) and there was no interaction with TestLang ($F_{1,342} = .55, p = .46$). There was a main effect of Gender ($F_{1,342} = 21.00, p < .001, \eta^2 = .06$), with girls outperforming boys and no interaction with TestLang ($F_{1,342} = .14, p <= .71$) (see Figure 3).
Linear mixed models were then carried out with fixed effects only for those predictors that reached significance in the aforementioned ANCOVAs, with random slopes and intercept for Language Community and random intercepts for participants. Separate models were conducted for each fixed effect variable, with significance assessed by comparing each model against a null in which the fixed effect was absent. Linear mixed models were calculated using the lme4 package (Bates, Maechler, Bolker, & Walker, 2014) in the R environment (R Development Core Team, 2006, version 0.99.896). The coefficients for each model are given in Tables 11 (comprehension) and 12 (production). Note that the effect that is tested in these comparisons is the combined main effect and interaction with TestLang if one was indicated by the ANCOVAs.

For comprehension there was a significant effect of LEQ ($\chi^2(2) = 18.02, p < .001$) and Overheard speech ($\chi^2(2) = 18.62, p < .001$) but no effect of Income ($\chi^2(1) = 1.60, p = .21$). For production there was a significant effect of LEQ ($\chi^2(2) = 18.75, p < .001$), Overheard speech ($\chi^2(2) = 23.59, p < .001$) and Gender ($\chi^2(1) = 13.26, p < .001$). When these analyses were conducted again with each significant fixed effect entered into a model already containing the other significant fixed effects (Table 13), the last entered fixed effect retained its significance ($p < .006$) in each case. Because we consider the linear mixed models to be the more
appropriate significance test for a model that generalises to all bilinguals (Study 3), Income was discarded as a predictor for subsequent analyses. The remaining predictors at the end of Step 1 were the relative amount of exposure to English in child-directed speech (LEQ), the proportion of English in parental overheard speech (Overheard speech), and Gender. This first step allowed us to confirm the robustness of predictors from the literature for the building of a model of the child’s lexicon (Study 2), based on data from the 13 target Additional Languages learners.

**Step 2 - Secondary predictors.** Secondary variables were then added to ANCOVAs containing those predictors shown to be significant in the Step 1 analysis above (LEQ, Overheard speech and Gender), with the 30 words common to all CDIs as dependent variables. These predictors were all the mode of exposure variables, and the three Linguistic Distance variables.

Mode of exposure variables were assessed by adding them individually to ANCOVAs containing LEQ, Overheard speech and, in the case of production, Gender. Societal status (variable Status), degree of language use consistency in parents’ input (variable Consistency), presence of siblings (variable Siblings), and number of parental native Additional Language speakers (one or two; variable FamLang) were added to a model containing TestLang as a within–subjects factor. Models with only Additional Language or English test scores omitted the factor of TestLang but included factors describing the native input of test language (variables PropEngN and PropALN), the number of sources of test language (SourcesEng and SourcesAL), and the amount of day care provided in the test language (EngDaycare and ALDaycare).
Only two variables achieved significance: Consistency and PropEngN (see table A7-1 in appendix 7). Consistency interacted significantly with TestLang in determining production scores ($F_{1,355} = 3.94$, $p = .047$, $\eta^2 = .01$), due to English vocabulary being boosted by a decreasing consistency in parents’ use of the two languages ($F_{1,355} = 6.07$, $p = .014$, $\eta^2 = .017$): the more parents used a mix of English and the Additional Language, and the more English vocabulary was produced. The proportion of parental native English spoken (PropEngN) significantly improved English production scores ($F_{1,296} = 4.12$, $p = .043$, $\eta^2 = .01$).

INSERT TABLE 14 HERE

The effect of Consistency on English production scores was confirmed with a linear mixed model ($\chi^2(1) = 5.79$, $p = .016$), however, owing to the very small effect size, this variable was not included in the UKBTAT predictive models. The effect of proportion of native English spoken on English production scores was not supported by a linear mixed model ($\chi^2(1) < 1$), and was not retained in the UKBTAT equations.

Finally, the three Linguistic Distance variables were assessed, phonological overlap, word order typology and morphological complexity. Because these showed a perfect to very high association with Language Community, these factors could not be added to ANCOVAs and were assessed in linear mixed models only (see Tables 15 to 17). These revealed a significant effect of Phonological Overlap on Additional Language production ($\chi^2(1) = 4.61$, $p = .032$), a significant effect of Word Order typology on Additional Language comprehension ($\chi^2(1) = 6.02$, $p = .014$), and a significant effect of Morphological Complexity on Additional Language comprehension ($\chi^2(1) = 4.80$, $p = .028$). In all three cases, an advantage was found for children learning an Additional Language close to English. No effects on English were seen.
In summary, all variables but two (Consistency and PropEngN) from Step 2 analyses were excluded at the ANCOVA stage, due to lack of significance. Consistency did have a significant effect in the subsequent linear mixed models but its effect size was too small to warrant integration in the UKBTAT predictive models (Study 2, next Chapter). PropEngN (proportion of English that is native) failed to reach significance in the linear mixed models, and therefore will not be included in the UKBTAT models. All measures of Linguistic Distance were found to be significant in the linear mixed models, fulfilling the predictions of Study 1. It must be kept in mind however that all results obtained at Step 2 should be taken in the context of multiple comparisons and viewed as subject to confirmation in future studies.

Metrics of linguistic distance will not be included in the UKBTAT models (Study 2) because our aim was to build a predictive model for any bilingual child learning British English (Study 3), and measures of linguistic distance will not be available for any Additional Language different from our 13 target languages.

**Comparison with full CDI.** The effects found in the Step 1 analysis were checked in the full CDI data (the proportion of words in the 100-word Oxford Short Form CDI and in the original Additional Language CDIs). The pattern of significance was identical with effect sizes highly comparable. In particular, linear mixed models once again showed no effect of Income on comprehension ($\chi^2(1) = 1.36, p = .24$).
On a final note, in the analyses provided in this paper, we have deliberately ignored item-level analyses as they are beyond our current scope (but see Table A5-2 in appendix 5 for a breakdown of comprehension and production of each English word in the 30-word CDI, as a function of exposure). However, further analyses at this level would provide a privileged insight of the internal organisation of the bilingual lexicon, complementing pioneering studies regarding the processes by which new words are added to the lexicon in monolinguals (e.g., Hills, Maouene, Maouene, Sheya, & Smith, 2009) or bilinguals (Bilson, Yoshida, Tran, Woods, & Hills, 2015). By comparison, where Bilson et al. (2015) collected data in 181 children spanning the age of 6 months to 78 months from eight different English-Additional Language pairs, using a version of the MCDI Toddler form designed for children aged 16 to 30 months of age (Fenson et al., 2007), our dataset includes data for both English and Additional Language (when available) from 430 24-month-olds, collected using age-appropriate tools. One application of this data now currently being conducted is to examine whether phonological overlap modulates the 2-year-old bilingual lexicon in terms of associative relationships and frequency for translation equivalents.

**Key Findings**

The aim of Study 1 was to establish whether measures of linguistic distance could predict vocabulary size at age 2 in bilingual toddlers. To achieve this, we first showed that vocabulary size was modulated by a set of robust factors from the literature: relative amount of exposure to English versus the Additional Language (English and Additional Language comprehension and production), proportion of English in overheard speech (English comprehension and production) and gender (English and Additional Language production). Two other, less established predictors emerged: first, English production was boosted when each parent used a mix of languages as compared to using one language only – but due to its very small effect size this variable will not be included in the subsequent UKBTAT equations.
Second, the proportion of native English spoken by parents significantly improved English production scores – but this effect did not survive in linear mixed models and therefore will not be included in the UKBTAT. No other variables reached significance, in particular not SES.

Importantly, we found that the three measures of linguistic distance predicted vocabulary knowledge in two-year-olds learning British English and one of 13 target Additional Languages, above and beyond variance due to Language Community: phonological overlap, SVO order typology and morphological complexity. Specifically, we found that children learning a language phonologically close to English had a larger production vocabulary in their Additional Language; similarly, those learning typologically or morphologically close languages to English had a larger Additional Language comprehension vocabulary.
Chapter 4 - Results for Studies 2 and 3: The UKBTAT Model and its Application to Non-Target Additional Language Learners

The aim of Study 2 was to develop the UKBTAT (UK Bilingual Toddlers Assessment Tool), the first screening tool for assessing the vocabulary size of bilingual 2-year-olds, in this case learning British English and one of the 13 target Additional Language. The aim of Study 3 was to establish the reliability of UKBTAT for bilingual children learning British English and any other non-target Additional Language. Norms for bilingual vocabulary in English were obtained through regression equations in linear mixed models, using variables shown to be predictive of comprehension and production in the previous analyses (Chapter 3). Similarly, norms for the Additional Language vocabulary were calculated for children learning one of the 12 target Additional Languages (Spanish is sadly absent from the final list of target languages due to some disagreement with the Spanish CDI editors, TEA Ediciones).

Study 2: Characteristics of the UKBTAT

To be made freely accessible online at www.psy.plymouth.ac.uk/UKBTAT for professionals working with young children and academics, the UKBTAT is similar to the platform used for data collection in this project, but with modifications suited to an applied setting. Firstly, access is secured for practitioners or academics through a personal account, allowing confidential storage of patient test results. Practitioners can use the system to send a link to parents requesting the completion of tests, and have full access to all responses if required. Alternatively tests can be printed and used offline with parents. The tests are still presented in the same order as in this study, with English 100-word Oxford Short Form CDI, full Additional Language CDI (when Additional Language is one of the supported target languages), finishing with the Plymouth Language Exposure Questionnaire. The Plymouth Language Exposure Questionnaire is still the last component that must be filled in by the
practitioner, either on the phone or in a live interview with the parent(s). Many of the questions from the family questionnaire and the Plymouth Language Exposure Questionnaire have been merged in an abbreviated Plymouth Language Exposure Questionnaire, which retains only the questions relevant to the significant predictors (amount of exposure, gender, overheard speech).

In the UKBTAT all children are assessed in English, with those whose Additional Language is one of the 12 target languages also assessed in their Additional Language. This data is used to calculate a percentile score for the child’s position in their cohort for expressive and receptive vocabulary. For children whose Additional Language is assessed, separate ratings are provided for each language, otherwise only a single rating is provided for English.

**Study 2: UKBTAT Predictive Equations**

In order to be included in the UKBTAT model, predictors were required to reach significance in the ANCOVAs and the subsequent linear mixed models, and have an effect size of at least $\eta^2 = .02$ in the ANCOVAs (see Chapter 3). With these criteria, predictors that made it through Step 1 were the relative amount of English child-directed speech (LEQ), the proportion of English in parental overheard speech (Overheard speech) and Gender. No predictor relating to SES, the source of each language, the properties of the input and the status of the Additional Language survived Step 2 analyses. From the outset, we ruled out including Language Distance predictors in the equations since our aim was to provide models applicable to any Additional Language (Study 3).

Coefficients were obtained from the final mixed models shown in Table 18. In the case of English, these were obtained from a model run on the full cohort of 430 children, and on the 100-word Oxford Short Form CDI data rather than the 30-word CDI, in order to improve representativeness for the UKBTAT implementation (as mentioned before, the 30-
word CDI shows a ceiling effect for a third of children in English comprehension). For the Additional Languages, the coefficients were obtained from models run on the 372 children who provided Additional Language data, and on the 30-word CDIs.

INSERT TABLE 18 HERE

Altogether, these equations provide predicted scores for a bilingual of unspecified Additional Language in English, and in the Additional Language if it is part of our 12 target languages (Table 19).

INSERT TABLE 19 HERE

For example, an Italian-English girl has 50% exposure to English (LEQ = 50) with parents speaking English and Italian equally often between themselves (Overheard speech = 3; this variable uses a 5-point scale, with 1 = parents always use the Additional Language when addressing one another, 2 = usually the Additional Language, 3 = English about half the time, 4 = usually English, 5 = always English; see Appendix 2). Using the coefficients from the row label “Predicted English 100 score” in Table 19, the equation to be used would be 37.62 + 0.23 x LEQ + 5.19 x Overheard speech. Replacing LEQ with 50 and Overheard speech with 3, the child should have a predicted English score of 64.7 in comprehension, meaning she should understand 65 words from the 100 word Oxford Short Form CDI. Similarly, she obtains a score of 45.9 in English production using the appropriate equation in Table 19, meaning she would produce 46 out of the 100 words from the English Short Form CDI. In the Additional Language she obtains 18.83 in comprehension and 12.02 in production, meaning she should understand 19 words in Italian from the 30-word Italian CDI and produce 12.
As a diagnostic tool, it is important to be able to interpret the difference between a child’s predicted and observed scores as a percentile. A reasonable threshold for suspecting a language delay is a score within the 10th percentile (Fenson et al., 2007; Rescorla, 2002; Tomblin, Records, & Zhang, 1996), so access to these ratings will allow practitioners to make an informed decision as to whether a referral might be necessary in a near future, or whether a wait and see approach is more appropriate.

We therefore examined the distribution of observed - predicted residuals in the mixed models from which the coefficients above were generated. Standard deviations of these residuals were as follows: English comprehension 21.19, English production 22.28, Additional Language comprehension 6.04, Additional Language production 7.60. These provide a basis for converting an observed - predicted difference scored in items into a percentile, which is what UKBTAT reports for a child screened by this tool. Thus in English comprehension, an observed - predicted decrement of 21.96 items places a child at exactly the 15th percentile, and a decrement of 27.16 items at exactly the tenth percentile. In the example above, if the Italian-English girl who was predicted an English comprehension score of 64.7 words scored in reality less than 42.7 (that is, 64.7-21.96), she would be in the 15th percentile (see Table 8).

Figure 4 provides the percentiles of word comprehension and production in English, illustrating the gender effect in production, and the well-documented difference between bilingual scores and monolingual data.

INSERT FIGURE 4 HERE
It is worth pointing out that a common practice recommended by Rescorla (1989), known as the Delay 3 cutoff, is to refer for further assessment any (American English) monolingual 2-year-old child who produces fewer than 50 words from the LDS (which contains 310 words, therefore 16%), which identifies about 15% of children. Our findings clearly point to the infeasibility of this “one size fits all” approach for bilingual children: the English vocabulary production score that would be needed to be in the 15th percentile or below varies between 0 and 42.3 (out of 100), depending on the extreme values of the predictors. That is, a boy with the minimum exposure to English, and whose parents would always speak the Additional Language between them, should produce on average 14.0 words out of 100 on the English CDI, and a score of 0 would put him on the 15th percentile. In contrast, a girl hearing 100% English as measured by the LEQ and whose parents always speak English between them, should produce 65.6 on the English CDI, and a score of 42.3 would place her on the 15th percentile.

**Study 3: Testing the Predictive Model**

We tested the validity of the equations above by seeing how accurately they could be used to predict novel data, namely those of the 58 non-target Additional Language children, which was the aim of Study 3. Predicted scores for these children were generated using the equations (recalculated for the 372 children learning a target Additional Language) and then correlated with the observed scores. This was done for English scores only since non-target children had supplied no Additional Language data. For both comprehension and production, strong correlations were seen between predicted and observed scores (comprehension: $r = .60$; production: $r = .59$). Importantly, there was not any systematic under-prediction or over-prediction of scores in these novel data, as established by t-tests of the means of observed and predicted scores ($t < 1$).
We also calculated the number of children who would be identified as having a delayed language acquisition, by applying the conservative criterion of scoring less than 1 SD (16th percentile) below the mean of the overall distribution (Conti-Ramsden, Botting, & Faragher, 2001). For each child in the 58 non-target Additional Language learners, using the standard deviations of residuals calculated above (UKBT predictive equations derived from the 372 children leaning the target Additional Languages), we converted the difference between each predicted score and the observed score as a percentile. Out of the 58 children, 9 were at or below the 16th percentile (15.5%) in comprehension and 11 in production (19.0%). Five out of the 9 children with low comprehension scores had production scores at or below the 16th percentile, with the other 4 scoring also relatively low in production. Two children scoring very low on production had normal comprehension scores. Given the prevalence of 7-15% of experiencing delayed language acquisition (Kohnert, 2010) in monolingual children, these results suggest a very satisfactory sensitivity for the UBTAT equations.

This demonstrates that the model was not simply fitted to UKBT data a posteriori, but also has predictive validity, not only to fit a new set of data, but also to identify children with potential language delays. Furthermore, as the key test of the validity of our norms was carried out with data from children outside of the range of Additional Languages used to develop the model, it shows that the model is predictive of general bilingual vocabulary, whatever Additional Language is spoken by the British-English learning bilingual. We therefore conclude that we have developed bilingual norms for 24-month-olds learning British English and any Additional Language, which have clear cut-offs for referral once the proportions of English in child-directed input and parental overheard speech have been determined, fulfilling the objectives of Studies 2 and 3.
Chapter 5 - General Discussion

Ours is the first study to directly measure the relative contribution of linguistic distance to the acquisition of a bilingual toddler's two languages, which was the aim of Study 1. To address this question we tested 372 24-month-olds learning British English and one of 13 target Additional Languages. We found that a higher phonological overlap between these Additional Languages and British English led to higher levels of Additional Language CDI vocabulary production. Similar effects in comprehension were found for our other measures of linguistic distance, namely degree of similar in morphological complexity and word order. Importantly, linguistic distance contributed unique variance even when other key factors (proportion of English in child-directed input, proportion of English in parental overheard speech and gender) were entered into the same model.

Ours is also the first study to develop bilingual norms specified for the proportion of a particular language that a child hears in the input, which was the objective of Study 2. To establish the reliability of our norms, we applied the model developed with the 372 24-month-olds learning British English and one of 13 target Additional Languages, to a cohort of 58 24-month-olds learning British English and an Additional Language which was not part of our 13 target languages. We found that the English vocabulary scores derived from the model were highly predictive of the vocabulary scores of these 58 children, showing a strong validity of our model for estimating word knowledge in any bilingual toddler growing up in the UK, which was the aim of Study 3. This demonstrates the feasibility of assessing bilingual toddlers in the majority language only, providing professionals working with young children with a practical solution to a long-standing problem in societies where bilinguals come from heterogeneous backgrounds.
Study 1: Linguistic Distance and the Bilingual Lexicon

To explore the effect of linguistic distance on vocabulary outcome, we were faced with the problem of disentangling variance due to linguistic distance from that due to cultural diversity amongst language communities. In our initial analyses we treated our 13 target language pairs as a random factor. This provided an excellent fit between predicted and observed values from bilinguals learning an Additional Language outside of our 13 target languages, indicating that this factor should be included in any future study using heterogeneous sampling of bilinguals. In our second analysis we replaced the random effect of language with a linear predictor of linguistic distance, as measured by the phonological overlap between English words and their translation equivalents in the Additional Language. We found that children’s production of Additional Language words was improved when this language was phonologically close to English (such as Dutch, Welsh, German) as compared to more distant languages (such as Cantonese, Polish and Greek). Testing other measures of linguistic distance, we found that children have a receptive vocabulary boost in their Additional Language if they learn a language with the same word order typology as British English (such as Polish or Portuguese) and/or a morphologically close language (such as Cantonese or Mandarin).

Phonological overlap distance. In the literature the possibility that bilinguals do not face the same learning challenges depending on the language pairs being acquired is rarely acknowledged (but see Argyri & Sorace, 2007). Here we established that linguistic distance between a bilingual child’s languages shapes their word learning at the age of two. This finding is perhaps less surprising given the recent growing evidence from monolingual research showing that young learners follow slightly different paths in speech perception (e.g., Mani & Plunkett, 2010; Nazzi, 2005), segmentation (e.g., Höhle et al., 2009) and lexical growth (e.g., Bleses et al., 2008) depending on the language they acquire. It is also
supported by research examining adult bilingual lexical access which has investigated the
effect of lexical overlap of translation equivalents on lexical access (e.g., Costa, Caramazza,
& Sebastián-Gallés, 2000; Strijkers, Costa, & Thierry, 2009). Cognates, translation
equivalents with form overlap, such as bed and Bett in German, are known to provide an
advantage to production, similar to the linear measure of phonological overlap used in the
current study. In word production, cognates are produced faster (e.g., Costa et al., 2000;
Hoshino & Kroll, 2008), elicit a different brain signature (e.g., Strijkers et al., 2009), and
produce higher levels of activation in priming tasks (e.g., Colomé & Miozzo, 2010) than non-
cognates. The cognate advantage in picture naming is also found in young proficient
bilinguals as early as 4 years (Sheng, Lam, Cruz, & Fulton, 2016; see also Poarch & van Hell,
2012).

To explain this advantage it has been proposed that cognates have different
representations than non-cognates in the lexicon, perhaps because of a larger conceptual
overlap (van Hell & De Groot, 1998), a shared morphological representation (Sánchez-Casas
& García-Albea, 2005), or because they might have been learned earlier (Costa, Pannunzi,
Deco, & Pickering, 2016). Alternatively, it has been proposed that the cognate advantage is
the by-product of the dynamic interactions between the lexical and the phonological (and
orthographical) levels of processing within the lexicon (Costa, Sanesteban, & Caño, 2005).
Altogether, these findings with cognates show good equivalence with our own findings,
where phonological overlap between translation equivalents increased Additional Language
expressive vocabulary. This finding also provides support to the proposal that the cognate
advantage is due to cognates being acquired before non-cognates in early childhood (Costa et
al., 2016), leading to an ease of processing later in life.

Finally, the cognate advantage is an emerging property of recent computational
models of the bilingual lexicon (BLINCS: Shook & Marian, 2013; DEV-LEX II: Zhao & Li,
2010): the activation of a concept in a common semantic lexicon during word production would generate parallel top-down activation of phonological representations from lexical representations in both languages. Any segments that overlapped between language representations would receive top-down activation from both of the languages lexical representations. This would provide an advantage to cognate or more overlapped translation equivalents, as they would become activated faster than those with less or non-overlapped representations (see also Costa et al., 2005).

One aspect of our results worth noting is that, although we found an increase in Additional Language vocabulary with phonological overlap in production, we found no effect in comprehension. This disparity also has some parallels in prior literature, where the evidence for a cognate advantage in bilingual spoken word recognition is mixed (see a review in Lagrou, Hartsuiker, & Duyck, 2011; see the review by Sánchez-Casas & García-Albea, 2005, for the cognate effect in visual word recognition). Although there is evidence for non-selective lexical access in word recognition as is found in production (Lagrou et al., 2011), that is, for online activation of words in both language, Shook, Goldrick, Engstler and Marian (2015) did not find any cognate advantage in a word recognition task in spoken English sentences in German-English bilinguals. When using an eye-tracking word recognition task for sets of pictures, Blumenfeld and Marian (2007) reported a cognate advantage dependent on the listener’s proficiency in the target language. That is, whereas a cognate and non-cognate equally activate words in a highly proficient language, only cognates boost the activation of words in a less proficient language. In development all prior studies of cognate advantage in spoken word recognition have been with Spanish-English bilinguals. Again, findings are mixed, with some studies not finding any advantage in receptive vocabulary recognition (in first graders: Umbel, Pearson, Fernandez, & Oller, 1992; first to sixth graders: Umbel & Oller, 1994), while others did find an advantage (fifth and sixth graders:
Cunningham & Graham, 2000; 8 to 13 years old: Kelley & Kohnert, 2012; kindergarten and first graders: Pérez, Peña, & Bedore, 2010). Kelley and Kohnert (2012) actually directly compared the cognate effect in production and comprehension using standardised tests, and found a very small advantage in comprehension, and a small to medium effect in production. In comprehension a large proportion of the variance in the cognate advantage was due to age, with older children showing a greater advantage than younger ones.

In sum, our findings are the first to demonstrate that phonological overlap at the lexical level appears to boost the acquisition of expressive vocabulary in bilingual toddlers, which fits nicely with past demonstrations of a cognate advantage in older children and adults.

**Syntactic and morphological distance.** Our findings of a facilitatory effect of word order typology distance on receptive vocabulary can be explained in three, non-exclusive ways. First, children learning two languages with the same word order, such as British English and Polish, can probably use similar phrase-level prosodic cues for segmentation of syntactic constituents: indeed VO languages (such as English and French) primarily use duration to express prosodic prominence of a content word as compared to a functor, while OV languages (such as Bengali and Hindi) tend to use pitch/intensity (Nespor et al., 2008). The search for similar cues in the speech signal would lead to a single mechanism for prosodic-driven segmentation, boosting the retrieval of words and the assignment of syntactic categories. An additional explanation of this facilitatory effect is that, instead of activating both languages, bilinguals transfer the structure of their native language processing to that of the new language (Costa et al., 2016). Although this proposal applies to lexical processing in sequential bilinguals, the idea that a processing structure for one language can be ‘carried over’ to the other language also has currency for word order computation. Finally, some studies have proposed that word order variations amongst the world’s languages are constrained by computational or learnability limitations, leading to a proliferation of easy-to-
learn orders (e.g., Ferrer-i-Cancho, 2015; Lupyan & Christiansen, 2002). In this perspective, pairs of languages that differ on the word order dimension will add to the learnability issue by adding computational complexity.

In addition to word order typology we also found a facilitative effect of morphological similarity, with children learning Additional Languages morphologically close to English, such as isolating Cantonese or Mandarin, having better Additional Language comprehension vocabulary than those with a distant Additional Language, such as the agglutinative Bengali. In monolingual research, it has been argued that complex morphological systems may hinder language acquisition (e.g., Slobin, 1973) - although complex systems can be learnt quickly provided that morphological rules are regular and obligatory (e.g., Devescovi et al., 2005; Kim, McGregor, & Thompson, 2000). Our findings suggest that bilinguals learning languages with similar morphology may benefit from the training of cognitive resources engaged in supporting the learning of one kind of morphology over another, for example, memory for isolating languages, versus rule-based learning for synthetic languages, as suggested by Fortescue and Lennert Olsen (1992). Some aspects of this cognitive training might be driving the bilingual cognitive advantage (Bialystok, 2009), raising the interesting possibility that linguistic distance could be partially responsible for the elusive nature of this cognitive advantage (Paap & Greenberg, 2013).

On a final note, when considering these findings it should be noted that language distance was found to modulate Additional Language scores only, with English scores being more resistant to facilitatory effects from the Additional Language proximity. We interpret this as showing that English acquisition benefits from the overarching effect of the English-speaking environment, whereas the Additional Language acquisition relies, in most cases, solely on one or two parents’ input. While measures of exposure do not quantify the weight of everyday social interactions (shopping, visit to the doctor, media exposure, etc), a telling
outcome that can be derived from Figure 1 is that in order for a bilingual child from our corpus to know an equal proportion of words in English and Additional Language, her/his exposure to English as measured by the Plymouth Language Exposure Questionnaire only needs to be at 30% of English in comprehension (they would then know 23 out the 30 common words in English and the Additional Language) and 20% in production (they would then produce 14 out of the 30 common words in English and the Additional Language). These low English exposure values clearly fail to capture the overwhelming influence of the language of the surrounding community, and point to the relative vulnerability of the growth of the Additional Language.

In this study we have focussed on three measures of linguistic distance, phonological overlap of the child lexicon, syntax typology and morphological complexity, that reflect the core aspects of language development in the second year of life. However, ‘linguistic distance’ is fundamentally complex, with a multidimensional representation that goes beyond the factors examined thus far. Our database provides an opportunity to continue the exploration of how additional measures of linguistic distance can account for variations in bilingual vocabulary, for example, through examination of the effect of prosody on early word development (e.g., rhythmic families, final word lengthening, etc; White et al., in prep), or the effect of cross-linguistic differences in infant-directed speech styles (e.g., Fernald et al., 1989).

In conclusion, the finding that linguistic distance shapes vocabulary knowledge in the early years strongly supports the idea of independent (Genesee et al., 1995), yet interfering language systems from the onset of development (DeAnda et al., 2016, Von Holzen & Mani, 2012). It is unknown at this stage whether the facilitation effects we found for phonologically or structurally close languages are due to the sharing of information processing mechanisms, or to the duplication of processing structures from one language to the next, following the
idea of a transfer proposed by Costa et al. (2016). Further research will be needed to discover
the mechanisms underlying language transfers in early childhood, in order to shed some light
on how the brain organises information sharing when two systems compete for resources.

**Study 2: Predicting Vocabulary Scores in Bilingual Toddlers**

The second key aim of the current paper was to develop a model of English and
Additional Language vocabulary to be used with UK-raised bilinguals learning one of the
target Additional Languages. To this aim we investigated which predictors should be
included in this model, out of an extensive inventory which we summarise below (see also Table 1).

**Relative amount of exposure to languages.** As expected, the most robust predictor
of English and Additional Language vocabulary was found to be the relative amount of
exposure to child-directed English versus the Additional Language (e.g., Hoff, 2003). This
was predictive of both comprehension and production, with greater exposure to English
increasing vocabularies in English, and reducing them in the Additional Language. Similarly,
the proportion of English/Additional Language spoken *between* parents was also strongly
predictive of comprehension and production in English, in line with previous studies showing
that children encode information from overheard speech (Akhtar, 2005; Shneidman, Arroyo,
Levine, & Goldin-Meadow, 2013).

**Mode of Exposure.** We explored the predictive value of factors related to the source,
properties, and status of the mode of exposure to English and the Additional Language. Only
the two predictors related to the properties of the input survived our analytical process - yet
statistical criteria prevented their inclusion in the final predictive models: the proportion of
native English spoken to the child by parents, and the degree of language use consistency in
parents’ speech.
Source of each language. First we examined whether the fact that two parents were native Additional Language speakers, or only one, had an impact on vocabulary knowledge, as was suggested by findings by Barrena et al. (2008). This factor did not have any significant impact in our data, perhaps because much of the variance associated to this variable was already apportioned to the relative amount of exposure to each language.

Second we looked at whether the total number of native English speakers, or the total number of Additional Language speakers around the child would affect word knowledge in each language. This was previously found by Gollan et al. (2015), testing 8-year-old Hebrew-English bilinguals in a picture naming task, who reported that children interacting with more Hebrew speakers could name more pictures in this language (see also Place & Hoff, 2011). However Place and Hoff (2016) only reported modest effects of the number of speakers in Spanish-English 30-month-olds, and only in Spanish. Here we did not find any significant advantage for being surrounded by many native speakers. Further research is needed to clarify the impact of this factor on vocabulary growth, as it is of major theoretical interest to delineate the role of input variability in phonological development (Rost & McMurray, 2009).

Thirdly we found no effect of the time spent in daycare (in each language) on vocabulary development. Given that daycare attendance in monolingual children tends to benefit only those from low SES (Côté et al., 2013), and given that our sampling failed to capture a significant portion of low SES families, it is perhaps not surprising that we did not report any effect of this factor.

Finally, regarding the effect of the number of older siblings, predictions from the literature were mixed, with monolingual data pointing to larger vocabularies overall in first-born children (Huttenlocher et al., 2010), and bilingual studies suggesting larger English vocabularies for North American bilingual toddlers with older siblings (Bridges & Hoff, 2014). Here we did not report any significant effect of this factor, which perhaps is related to
the fact that in our data collection we did not distinguish between toddlers who had school-aged siblings and toddlers whose siblings were still too young. Indeed Bridges and Hoff (2014) reported that it was school-aged siblings who were mainly responsible for an increase in the proportion of English spoken at home and the resulting increase in toddlers’ English vocabulary.

**Properties of the input.** We found that English production increased with the proportion of native English parental input, in line with previous findings that native speakers provide more supportive linguistic input than non-natives (Hammer et al., 2012; Place & Hoff, 2011, 2016; although see Paradis, 2011, who found no effect). Fernald (2006) suggested that non-native speech might hinder the development of phonological categories, but this appears contradicted by the fact that we did not report any negative effect of non-native input on vocabulary. Our findings may be better accounted for by non-native speakers using less varied vocabulary than native speakers, as suggested by Hoff et al. (2013).

Finally, we found that the degree of language use consistency in parents’ speech was positively associated with English production, so that children whose parents used a mix of the two languages knew more words in English, perhaps because more code-switching increases the relative frequency of the majority language. However, previous findings on the impact of within-speaker consistency (measured at the sentence level as in code-switching, or at the discourse level as in the degree of language use consistency) suggest mixed outcomes: Byers-Heinlein (2013) reported a detrimental effect of code-switching at 18 months, but only marginally at 24 months, whereas Place and Hoff (2016) reported no robust relations between the degree of language use consistency in mothers’ speech and language development at 30 months. In addition to an age-related explanation, we argued that the discrepancy between these two prior studies would be due to language distance, as Byers-Heinlein tested mainly distant languages learners whilst Place and Hoff examined close languages learners. To
examine whether the positive effect found in the current study was different for close and
distant language learners, we ran separate post-hoc regression analyses on the median split of
children learning close (N = 240) and distant (N = 132) languages (based on phonological
overlap). For distant language learners, the degree of language use consistency in parental
speech did not predict comprehension nor production, once corrected for exposure to English
and the proportion of English in overheard speech. However, for children learning close
languages, the degree of language use consistency in parental speech contributed significantly
to improve English production scores (main model: $F(4, 239) = 11.34, p < .001$; standardised
$\beta$ for language mixing = 0.15, $p = .016$; no effect for comprehension, or for Additional
Language scores). These results do provide some preliminary support for our original
hypothesis: distant language learners perform poorly with language mixing input measured
through code-switching (Byers-Heinlein, 2013) or show no effect (this study), while close
language learners either benefit from language mixing measured through language use
consistency (this study) or show no effect (Place & Hoff, 2016). The explanation behind
these findings would be that frequent switches from one set of representations to another in
the case of distant languages impinge on cognitive resources, whereas close languages
activate overlapping representations and therefore do not necessitate an increased cognitive
flexibility.

*Status of the Additional Language (societal vs. minority).* We hypothesized that the
societal status of the Additional Language would have consequences for children’s
achievements in the two languages, because of people’s more positive attitude towards
bilingualism, and also because of a more balanced exposure to the two languages in everyday
life. However, Welsh-English toddlers in Wales did not have significantly higher vocabulary
scores in their two languages than the other bilinguals, whether these scores were corrected
by situational factors or not. In the literature, Welsh-English bilinguals’ vocabulary in
English tends to be lower than English monolinguals’ (Rhys & Thomas, 2013) at the ages of 7 and 11 years, with a strong effect of language dominance (as defined by exposure and family language) and a complex relation between home language exposure, SES, and age (Gathercole, et al., 2016). Our study shows that this “bilingual difference”, previously found in Welsh, is similar to that of any other bilingual minority group in the UK, at least at the age of 24 months. This point contributes to strengthen the generality of the UKBTAT model for predicting language outcomes in any incoming bilingual toddler growing in the UK. Importantly, the fact that there was no effect for the societal status of the Additional Language being learned implies that our findings apply both to bilingual toddlers learning a minority language and also to those learning two languages which have more equivalent societal status, such as perhaps English and French in Canada.

Demographic factors (gender and SES). As expected, gender was found to be a reliable predictor of production vocabulary in both languages, with girls producing more words than boys (Huttenlocher et al., 1991); no effect was found on comprehension, which is also in line with previous findings (Eriksson et al., 2012).

Contrary to our initial expectations, SES effects were absent in our data, in keeping with prior studies which also had much reduced sampling at the low end of the SES spectrum (Fenson et al., 2007; Hamilton et al., 2000). The effects of these missing low SES children on the accuracy of UKBTAT norms are unclear. If they had been fully represented then we might have expected reduced vocabulary scores for low SES children, meaning that the current UKBTAT model would over-refer low SES children, and under-refer high SES children. There are a number of dangers with this assumption however, beyond those inherent in assuming that SES would have reached significance if provided with a fully balanced spectrum of samples. Fernald et al. (2013) reported that their SES effect, one of the strongest found in the literature, was stronger at the lower end of the SES spectrum. We confirmed this
with a re-analysis of data points retrieved from Fernald et al’s published scatterplot using the application Plot Digitizer (www.plotdigitizer.sourceforge.net), first reproducing the originally reported correlation of .34. We then went on to split this data at median SES and analyse high and low SES data separately, finding that the correlation of SES with CDI comprehension was significant in low SES children \( (r = .42, p = .001) \), but not in high SES children \( (r = .27, p > .05) \). The nonlinearity of this effect means that it would be poorly modelled by linear equations, such as those used in the UKBTAT.

In summary, the three factors that were identified to be the key predictors of vocabulary knowledge in 2-year-old bilinguals learning English and one target Additional Languages were the relative amount of exposure to English versus the Additional Language in child-directed input (English and Additional Language production and comprehension) and parental overheard speech (English production and comprehension), and gender (Additional Language and English production). The resulting models were built into the UKBTAT assessment tool, which fulfilled the objectives of Study 2. The UKBTAT uses measures of English vocabulary on the 100-word Oxford Short Form CDI, and if the child learns one of the target Additional Languages, the full Additional Language CDI is administered, from which the 30 words common to all CDIs are extracted to derive predictions. In addition, the features of the UKBTAT (online, based on parental report and interview) are particularly appealing for an initial screening at such an early age, where language assessments are notoriously challenging and yet very desirable to plan appropriate intervention.

**Application of the UKBTAT with Bilingual Children with Non-Target Additional Languages**

We created the UKBTAT norms for assessing the vocabulary of any bilingual 24-month-old learning British English and an Additional Language, regardless of which Additional Language it would be. These norms are available in British English, and in the
Additional Language when this is part of our target languages. The recommendations of professional bodies are that bilinguals should be assessed in both their languages as there is a, quite justified, risk that an individual child’s situational factors may render an assessment performed on only one language unrepresentative of their overall linguistic capability. Unfortunately, for pragmatic reasons due to the heterogeneity of additional languages spoken in the world - and in the UK in particular - this recommendation can only be followed in a relatively small minority of cases, with bilinguals generally only assessed in the majority language. Therefore, in this project we have sought to identify the situational factors that affect bilingual acquisition and quantify their contribution to improve the quality of English only testing, in the case of UK-raised toddlers. We have shown that only the relative amount of English exposure in child-directed input and overheard speech interacted with test language in the determination of vocabulary scores, thus we have no evidence that situational factors beyond these apply differently to the two test languages. This means there is no reason to suppose that Additional Language scores provide useful information beyond that of an English score, once corrected for these factors. Therefore, for clinical purposes, information provided by English vocabulary scores alone appears to provide an effective proxy for overall linguistic attainment, and can be safely used as normative data for any new incoming bilingual toddler. It is our hope that this pragmatic approach to bilingual screening will be generalised to other countries who are, like the UK, facing a growing number of bilingual infants from an increasingly heterogeneous background of languages.

**Limitations and Future Directions**

An important limitation of this study pertains to the relatively small proportion of children with a low level of exposure to English, either because of SES characteristics, date of arrival in the country or simply family characteristics. Regarding the poor representation of low SES families in our sample (only 4 children out of the cohort scored on the lowest
income band): as noted earlier, the current UKBTAT model would probably over-refer low SES children and, possibly, under-refer high SES children; only further research will allow to address this issue satisfyingly. Regarding date of arrival in the country, it must be noted that we did not include age of acquisition in the analyses, because the vast majority of toddlers were born in the UK (see participants section), which we took as a reasonable proxy for simultaneous acquisition, but it would be unreasonable to use the UKBTAT for a child whose age of acquisition of British English is only a few months prior assessment: not only is the effect of age of acquisition a very established predictor of bilingual development (Flege, Yeni-Komshian, Liu, 1999), but the Plymouth Language Exposure Questionnaire, which is implemented in the UKBTAT, does not provision (yet) for variation in the age of acquisition. Finally, the characteristics of the families included in the survey were such that only 7% of the 430 children had less than 10% exposure to English (as measured by the Plymouth Language Exposure Questionnaire). This probably relates again to the poor sampling of low SES families, and calls for caution in the use of the UKBTAT when assessing toddlers with very low English exposure.

In the same vein, another limitation relates to the mode of calculation of exposure to each language, which was here exclusively focused on the relative exposure (as most exposure questionnaires do: e.g., De Houwer & Bornstein, 2003; Paradis, 2011), and not on the quantity of exposure. That is, a child who scored 60% of English on our measure of exposure could experience a few hours of cumulated English speech per week or a few dozen, depending on the communication style of her caregivers. Measures of quantity (obtained through naturalistic recordings) are known to predict language growth in young monolinguals (Huttenlocher, Waterfall, Vasilyeva, Vevea, & Hedges, 2010), and thus a full measure of exposure should encompass both relative and absolute measures of language input.
Additional research will be needed to evaluate if quantity of bilingual exposure explains an additional portion of the variance in explaining vocabulary growth.

Another limiting factor relates to the age of toddlers, which we selected to be two years old, as an important milestone for parents, researchers and practitioners, in time for preschool referral if needed. Whether our key findings would hold for younger and older children remain to an empirical question, but we anticipate that measures of exposure and gender would remain central predictors of bilingual development throughout development (see Hyde & Linn, 1988 for effects of gender through development). What is more interesting is how linguistic distance metrics would predict language development before and after the age of two. Generally speaking, it is likely that the type of distance measures that would modulate bilingual language growth would depend both on the age of the child and to-be-assessed language skills, with perhaps phonological overlap metrics becoming less influential as grammar and morphology grow in the child. We are currently exploring these claims as a substantial subset of the cohort tested in this paper were re-assessed at age 3 with the same tools.

Finally, the language-specificity of our findings implies an obvious caveat, as the UKBTAT is currently valid only for UK-raised toddlers who learn British English as one of their languages. However there is no reason to think that the key results – that linguistic distance is predictive of vocabulary growth, and that a useful model of the early lexicon needs only a handful of predictors – would be language-specific. Of particular interest would be to replicate this cohort study in North America, as minimal adjustments to the 100-word Oxford Short Form CDI would be required, allowing the problem of assessing a growing number or bilinguals from heterogeneous populations (Statistics Canada, 2011; United States Census 2020) to be addressed.

**Conclusion**
The current research included three key strands of research questions. In the first study we established that linguistic distance between the two languages plays a role in predicting bilingual toddlers’ vocabulary at age 2, a result which moved the field forward. Given the interweaving of word-learning abilities and cognitive processes in development (Baddeley, Gathercole, Papagno, 1998), the impact of linguistic distance might extend beyond language acquisition, and could constitute a key factor in the study of the debated bilingual cognitive advantage (Bialystock, 2009; Paap & Greenberg, 2013).

In Study 2, which had an applied orientation, we identified the amount of exposure to each language in child-directed and overheard speech as key predictors of vocabulary development in bilingual toddlers, along with infant gender, and developed a model of the bilingual lexicon usable for assessment purposes, the UKBTAT. Finally, in Study 3, we explored the feasibility of assessing a bilingual toddler’s vocabulary in the majority language only, in order to provide professionals working with young children with a practical solution when encountering bilingual children from heterogeneous backgrounds, as is the case is most of the world. The validity of this approach was successfully demonstrated when the UKBTAT model was applied to a new cohort of bilinguals learning a different Additional Language to our original target languages. It is our hope that the UKBTAT will enhance the early detection of children at risk of language delays in the growing UK bilingual population, and perhaps in other countries where the same approach could be applied.

Table 3. Average phonological overlap between 406 British English words of the Oxford CDI and their translation equivalents for the 13 Additional Languages. The higher the number, the closer the languages. Word order typology distance to British English (1 = VO language like British English; 2 = VO/OV language; 3 = OV language). Morphological complexity distance to British English (1 = analytic/isolating language like British English; 2 = fusional; 3 = agglutinative).
Table 4. Mean amount of exposure to English versus Additional Language (AL) in child directed speech (LEQ) for each Additional Language group; proportion of English vs the Additional Language in maternal (or paternal) speech on a 5-point scale from 1 to 5 (MumPropEng and DadPropEng); proportion of English vs the Additional Language spoken between parents in overheard speech (Overheard speech; 5-point scale from 1 to 5; 1 = only Additional Language to 5 = only English). Details for non-target Additional Language children are provided under the row label “Other”. See appendix 3 for details of LEQ calculation, and Appendix 2 for details of calculation of the other variables.
Table 5. Characteristics of participants per Additional Language community in terms of mode of exposure (sources). Details for non-target Additional Language children are provided under the row label “Other”. Number of families where both parents are Additional Language speakers (Additional Language only) or only one (Mixed) (variable FamLang); Total number of regular English (or Additional Language) speakers around the child (SourcesEng and SourcesAL; observed range 0-6); weekly number of hours in an English (or Additional Language) speaking daycare (EngDaycare and ALDaycare); number of older siblings in the household (Siblings). See appendix 2 for details of the calculations of these variables.

Table 13. Coefficient estimates from the linear mixed models used in **Step 1 analyses** after the **ANCOVAs**, to estimate the robustness of each predictor when incremented onto models containing the other ones. Dependent variables are the scores on the 30-word CDIs in comprehension (English: CDI30Comp; Additional Language: ALCDI30Comp) and production (English: CDI30Prod; Additional Language: ALCDI30Prod). For variables which survived the **ANCOVA** stages and the initial linear mixed models with single predictors (tables 9 to 12), the coefficients for the full models are presented. Then for each variable of interest, such as LEQ, tests of significance ($\chi^2$) to compare the full model and its null are provided in the last two columns. TestLang = English vs Additional Language. $N = 372$. All variables were z-scored.
Table 14. **ANCOVA results for Step 2 analyses** (surviving predictors from Step 1 plus less well established predictors), restricted to those predictors providing significant effects. The dependent variables are scores in *production* on the 30-word CDIs (English: CDI30Prod; Additional Language: ALCDI30Prod). TestLang = English vs Additional Language. All variables were z-scored. The effect of Consistency (degree of language use consistency in parental speech, see Appendix 2) is calculated with \( N = 372 \). The effect of the proportion of native vs non–native English in parental speech (PropEngN) is calculated for \( N=313 \) due to 59 children for whom this variable could not be computed (see appendix 2).

Table 15. Coefficient estimates from the linear mixed models used in Step 2 analyses after the ANCOVAs, to estimate the effect of **Phonological Overlap** on vocabulary in each language, when incremented onto models containing the predictors retained from Step 1 analyses.

Dependent variables are scores on the 30-word CDIs in comprehension (English: CDI30Comp; Additional Language: ALCDI30Comp) and production (English: CDI30Prod; Additional Language: ALCDI30Prod). Tests of significance to compare each full model to its null (without the fixed effect of Phonological Overlap) are provided in the last two columns. 

\( N = 372 \). All variables were z-scored.
Table 16. Coefficient estimates from the linear mixed models used in Step 2 analyses after the ANCOVAs, to estimate the effect of **Word Order typology** on vocabulary in each language, when incremented onto models containing the predictors retained from Step 1 analyses.

Dependent variables are scores on the 30-word CDIs in comprehension (English: CDI30Comp; Additional Language: ALCDI30Comp) and production (English: CDI30Prod; Additional Language: ALCDI30Prod). Tests of significance to compare each full model to its null (without the fixed effect of Word Order) are provided in the last two columns. N = 372.

*All variables were z-scored.*
Table 17. Coefficient estimates from the linear mixed models used in Step 2 analyses after the ANCOVAs, to estimate the effect of Morphological complexity (Morph) on vocabulary in each language, when incremented onto models containing the predictors retained from Step 1 analyses. Dependent variables are scores on the 30-word CDIs in comprehension (English: CDI30Comp; Additional Language: ALCDI30Comp) and production (English: CDI30Prod; Additional Language: ALCDI30Prod). Tests of significance to compare each full model to its null (without the fixed effect of Morph) are provided in the last two columns. N = 372. All variables were z-scored.
Table 18. Coefficient estimates from the linear mixed models for the UKBTAT, for comprehension and production, in each language (English and the Additional Language).

Dependent variables are scores on the 100-word CDI in English (comprehension: CDI100comp; production: CDI100prod) and on the 30-word CDI in the Additional Language (comprehension: ALCDI30Comp; production: ALCDI30Prod). For English, the models were calculated with $N = 430$ children and with $N = 372$ for the Additional Language.

Variables were not z-scored so that they could be directly applied to new raw scores.

Table 19. Coefficients from the linear mixed models of vocabulary knowledge in English and the Additional Language, in comprehension and production, and decrements derived from standard deviations of residuals. For example, the predicted English score in comprehension is: $37.62 + 0.23 \times \text{LEQ} + 5.19 \times \text{Overheard speech}$, with LEQ ranging from 0 to 100 (proportion of exposure to English vs the Additional Language in child directed speech), and Overheard speech ranging between 1 and 5 (1 = parents always speak the AL between them; 2 = parents usually speak the Additional Language between them; 3 = parents speak the Additional Language and English half of the time; 4 = parents usually speak English between them; 5 = parents always speak English between them). Gender is assigned a value of 1 for girls and 2 for boys. Decrement is then applied to the predicted score, and compared to the observed score to determine if the child’s score is below the 10th or the 15th percentile.
Figure Captions

Figure 1. Vocabulary scores measured on the 30-words CDI as a function of the amount of exposure to English in child directed speech as measured by the LEQ (%). Top left: Additional Language comprehension; top right: Additional Language production; bottom left: English comprehension; bottom right: English production.

Figure 2. English vocabulary scores in comprehension and production measured on the 30-words CDI as a function of the proportion of English spoken between parents (Overheard speech). Overheard speech ranges from 1 (only Additional Language) to 5 (only English).

Figure 3. English and Additional Language vocabulary in comprehension (CDIComp) and production (CDIProd) on the 30-words CDI as a function of child’s gender.

Figure 4. Percentile values in English comprehension (left) and production (right) measured from the Oxford Short Form CDI, as function of gender, in the full cohort of bilingual toddlers (N = 430). For comparative purposes, monolingual data for comprehension and production are included on the same graphs (N = 125, taken from the Oxford CDI database, Hamilton et al., 2000). For example, in comprehension, children who understand a maximum of 50% of the CDI (Y axis) constitute about 75% of bilinguals, and 85% of monolinguals (X axis).

<tr>
<td>Proportion of native/non-native English (PropEngN)</td>
<td>This variable concerns input from parents only. The hours spent with each parent was computed as 168 – 7*Sleep – EngDaycare – ALDaycare – Hours alone with other parent (for 59 children this value was negative and PropEngN and PropALN could not be computed). Parents’ score on PropEng variable (1 to 5) was re-expressed as a proportion from 0 to 1 (1 = 0, 2 = .25, 3 = .5, 4 = .75, 5 = 1). This was multiplied by the hours the child spent with the parent to provide the hours of English input. If the parent was BE speaker this was native English input, if AL speaker this was non-native input. Both parents were assessed in this way. PropEngN was given by native English / (native + non-native Eng).</td>
</tr>
<tr>
<td>Proportion of native/non-native AL (PropALN)</td>
<td>As above, parents’ score on PropEng was expressed as a proportion from 0 to 1 (1 = 0, 2 = .25, 3 = .5, 4 = .75, 5 = 1), with this value then subtracted from 1 to provide a proportion of time speaking AL. This was multiplied by the hours the child spent with the parent to provide the hours of AL input. If the parent was AL speaker this was native AL input, if BE speaker this was non-native AL input. Both parents were assessed in this way. PropALN was given by native AL / (native + non-native AL).</td>
</tr>
</tbody>
</table>
Appendix 3 - Details of the Calculation of Percentage of English Exposure in a Typical Week in the Year Preceding Testing (LEQ, adapted from Cattani et al., 2014)

A. Input from the parents:
Number of hours a week in English-speaking nursery/childminder/playgroup = EngDaycare
Number of hours a week in an Additional Language speaking nursery/relatives = ALDaycare
Number of sleeping hours per night = Sleep
Does the mother always speak the Additional Language (AL) to the Child, or usually, or equally often English and the AL, or usually English, or always English (5 possible responses) = MumPropEng
Does the father always speak the AL to the Child, or usually, or equally often English and the AL, or usually English, or always English (5 possible responses) = DadPropEng
When together, who speaks most to the child? Mother, father or both = Most
Number of hours per week spent with mother only = HM
Number of hours per week spent with father only = HF

B. Calculations
1. Assign a percentage to M and F, to estimate the proportion of English in each parent’s input to the child.
   If MumPropEng (or DadPropEng) = Always AL then ME (or FE) = 100
   If MumPropEng (or DadPropEng) = Usually AL then ME (or FE) = 75
   If MumPropEng (or DadPropEng) = Equally AL and English then ME (or FE) = 50
   If MumPropEng (or DadPropEng) = usually English then ME (or FE) = 25
   If MumPropEng (or DadPropEng) = always English then ME (or FE) = 0

2. Correct HM and HF to give more weight to the time spent with the mother, as it is found usually that fathers tend to produce less verbal output to their child, therefore
directly impacting on the amount of exposure in English and the Additional Language (e.g., Pancsofar & Vernon-Feagans, 2006).

Corrected time with mother = CHM = HM*4/3

Corrected time with father = CHF = HF*2/3

3. Assign a value (MI to Most), to give more weight to the mother’s input. What is obtained corresponds to the percentage of the mother’s input during the time when both parents are with the child.

If Most = Mother then MI = 90
If Most = Father then MI = 50
If Most = Both then MI = 70

4. Calculate the number of hours per week with both parents together

\[ TBP = 7(24-\text{Sleep}) - \text{EngDaycare} - \text{ALDaycare} - \text{CHM} - \text{CHF} \]

5. Calculate the total number of hours of English exposure in a week (E) with the following formula:

\[
E = \frac{\text{CHM}(100-\text{ME})}{100} + \frac{\text{CHF}(100-\text{FE})}{100} + \text{EngDaycare} + 0.01*\text{TBP} - \frac{\text{MI}(100-\text{ME})}{100} + 0.01*\frac{\text{TBP}(100-\text{MI})(100-\text{FE})}{100}
\]

With English from mother when mother alone = CHM(100-ME)/100

English from father when father alone = CHF(100-FE)/100

English from mother when both parents together = 0.01*TBP*MI(100-ME)/100

English from father when both parents together = 0.01*TBP(100-MI)(100-FE)/100

6. Calculate the percentage of exposure to English

\[
P = \frac{E}{7(24 - \text{Sleep})}
\]

*Table A4. Number of bilingual children per language group (N = 58); they all learn British English and one of 26 Additional Languages which are not part of our 13 target Additional Languages.*
Table A5-1. List of words in the Oxford Short Form CDI and the 30-word CDI (in bold) in their order of presentation to parents.
Table A5-2. For words from the 30-word CDI, proportion of bilingual children (all 13 target
Additional Languages collapsed) who produce and understand each word in English.

Children’s data are binned as a function of exposure (as measured by the Plymouth
Language Exposure Questionnaire). For example, the word ‘ball’ is produced by 69.1% of
those children exposed to English between 0 and 25% of the time, and by 93.0% of those
children exposed to English between 75 and 100%.
