Abstract

Emboli, which are parts of blood clots, can be stuck in the vasculature of various organs (most frequently, lungs) and cause their malfunction or even death. In this work, using mathematical modelling, different types of emboli-like structures are studied in a double venous valve system. The model is implemented with a fully Lagrangian Discrete Multi-Physics technique and the flow is governed by flexible walls. The study shows the effect of different diameters and lengths of a free embolus in the flow surrounding the valve. The presence of an embolus strongly affects the dynamics of both the fluid and the leaflets in venous valves and the permanence of the embolus in the valve chamber is narrowly linked with its length.

Keywords: Discrete Multi-Physics, Smoothed Particle Hydrodynamics, Mass and Spring Model, biological venous valve, Emboli, Deep Venous Thrombosis.
1. Introduction

An embolus is generally formed when a section of a thrombus detaches and circulates in the cardiovascular system until reaching narrow vessels, most frequently, in the lungs [1-3]. When emboli are trapped, they can obstruct blood flow in the lungs leading to a potentially life-threatening complication known as pulmonary embolism (PE) or deep vein thrombosis (DVT). In the UK alone, around 25,000 deaths are caused by PE or DVT; this number is five times higher than those from breast cancer, AIDS and road accidents combined [4].

While medical research highlights the role of DVT on the hydrodynamics around venous valves [5], the actual physical interaction of the embolus with the valve remains unexplored. The literature provides a wide range of publications about venous and arterial thrombosis, but the majority of these studies focuses on thrombogenesis and clotting [6-14], rather than the dynamics of the embolus.

To circumvent the current limitations of in-vivo and in-vitro models, computer simulations (in-silico modelling) of the the venous valve have been carried out but, with a few exceptions [13, 15, 16], emboli are not accounted for. For DVT however, this represents a serious limitation since the presence of the embolus changes considerably the hydrodynamics around the valve.

Previous studies [15, 16] have shown that the diameter, the elasticity and the location of an embolus affect the flow in arterial bifurcations [15] or in Inferior Vena Cava (IVC) [16]. But the interaction of the embolus with more complex settings such as the flexible leaflets of the venous valve has not been investigated. Only Simão et Al. [13] consider the presence of solid...
particles in the venous valve, but these are simple Lagrangian point particles and the flow, therefore, is not fully resolved around them.

By modelling the physical interaction of emboli with different shapes and flexibilities with the soft leaflets of the venous valve and the change of hydrodynamics that this involves, this paper fills a gap in the literature since the valve environment is probably the most critical for DVT and the presence of clots in the vicinity of the valve has been associated with the occurrence of new thrombosis activation sites [5].
2. Methodology

2.1. Modelling

A hybrid approach, based on a particle framework, is implemented to model haemodynamics and solid structure deformation. The technique, called Discrete Multi-Physics (DMP) [14, 17, 18], associates Smoothed Particle Hydrodynamics (SPH) [19-21] and the Mass and Spring Model (MSM) [22-24] and has been used to model the fluid-structure interactions occurring in deep vein valves [14], cardiac valves [17] and the intestine [18].

In this approach, the liquid is represented by SPH particles that interact with each other by viscous and pressure forces and the tissues by MSM particles inter-connected by means of computational springs (to model the elastic modulus) and dashpots (to model viscoelasticity). The essential ideas behind the DMP method are summarized in Appendix A; the reader can refer to [24] for a more extensive explanation of the DMP theory and to [22] for applications in different fields such as lava flows, cell dynamics and solid-liquid flow.

2.2. Geometry

In this study, we use a 2D schematic representation of a double leg venous valve system. The geometry is similar to the short valve model [14] but here it is used with two antagonist valves (Fig. 1). The channel radius is $Z = 0.004$ m, the membrane length is $L = 0.01$m, the radius of the valve chamber is $R = 0.007$ m and its length is $Y = 0.04$ m [14]. The two valve systems are inter-connected and the total length between the two chambers is $C = 0.048$ m (0.046 m in [25]). The external walls are divided into four parts: two flexible sections where an external force is applied (Channel 1 and Channel 2 in Fig. 1), and two valve chambers.
(Valve chamber 1 and Valve chamber 2 in Fig. 1) that contain the leaflets. Since periodic boundary conditions are enforced, the fluid exiting from the channel opening on the right is reinserted to the channel opening on the left and vice versa. For the same reason, Channel 1 in Fig. 1 appears to be divided into two sections (one on the left and another on the right), but, computationally, the two ends are joined together by the periodic boundary conditions. A net fluid flow is achieved by means of external forces acting alternatively on Channel 1 and Channel 2 (Fig. 1). When a ‘squeezing’ force $F$ (see Fig. 1) is applied to Channel 1, Valve 1 opens, Valve 2 closes, and the fluid flows from the left to the right. When $F$ is applied to Channel 2, Valve 2 opens, Valve 1 closes, and the fluid maintains the same direction from the left to the right. This approach mimics the actual motion of blood in the legs’ veins induced by the contraction of the surrounding muscles.

In the rest of the paper, we refer to the regions between the leaflets (in both Valve 1 and Valve 2) as the ‘opening regions’ and to the regions between the walls and the leaflets (in both Valve chamber 1 and Valve chamber 2) as ‘sinus regions’ (Fig. 1).
According to the DMP approach (see Appendix A) both the fluid and the solid are represented by discrete computational entities, which we call ‘fluid particles’ and ‘solid particles’. The different behaviour of fluid and solid particles depends on the type of forces the DMP algorithm applies to each computational particle. If these forces model the viscous and pressure forces commonly acting on fluids, the computational particle behaves like a fluid; if they model the viscoelastic forces acting on solid, the particle behaves like a solid. Computationally, the fluid forces are calculated with the SPH method while the solid forces particles by means of springs (MSM model) as detailed in Appendix A. The wall delimiting the valve chamber is considered stationary and, therefore, no forces are applied to the computational particle representing this part of the domain. Solid-liquid boundary conditions are also modelled by means of inter-particle forces that model no-penetration and no-slip conditions as explained in Appendix A.

2.3. Model parameters

In our simulations, the geometry is divided into 168676 particles spaced of 10^{-4} m: 584 for the valves, 10722 for the walls, and 157370 for the fluid area. As mentioned, SPH particles are used for the fluid, stationary (solid) particles for the valve chamber walls and MSM particles for the flexible walls and the leaflets. Three layers of particles are used for the walls and two for each leaflet, with thicknesses of 3.10^{-4} m and 2.10^{-4} m, respectively. The flow is laminar [13, 25, 26] and blood is here considered a Newtonian fluid [15, 27]. Table 1 gathers all the parameters used in the simulation.

### 2.4. Simulation parameters

As detailed in Appendix A, the structure of the flexible tissue (wall and valve) and its elasticity are implemented with a spring model. The spring constant \(k_b\) has been chosen in order to model the different elastic properties of the leaflets and the walls (Table 1). A viscous coefficient \((k_v)\) is also added to the MSM springs to confer viscoelastic properties to the valve and the flexible wall as in a Kelvin–Voigt material.
The inlet/outlet of the fluid in the $x$-direction is controlled using periodic boundary conditions. The flow is pulsed periodically and generates several opening and closing of the valves. Therefore, we use the term “cycle” to define a single period including one opening and one closing of the same valve [25, 26]. For each cycle, we model the opening phase by applying a vertical force $F$ (Y-axis) on Channel 2 for 1.5 s while no force is applied to Channel 1 (Fig. 1). During the closing phase (1.5 s), Channel 2 is relaxed ($F$ on Channel 2 is set to 0) and $F$ is applied to Channel 1. The force $F$ is constant and uniform for each cycle (Table 1). For all simulations, a total of 10 cycles (30 s) are calculated.

2.5. Emboli

A solid, embolus-like structure is introduced into the flow. The solid particles of the embolus are joined together by springs whose Hook constant is reported in Table 2. Differently from some of our previous studies [14, 17] where the embolus grows due to an aggregation algorithm, here the embolus size is fixed during the simulation.

The effect of size, length and embolus’ flexibility is investigated (Table 2). In the literature, no standard size or length for emboli is given and the shape mostly depends on the surrounding flow, channel diameter and valve characteristics [13]. In this work, to account for a variety of potential cases, the selected sizes are in the range used by [16] and the lengths coincide with the length of (i) the sinus region (embolus L6 in Table 2), (ii) half of the valve chamber (embolus L19), (iii) the valve chamber (embolus L37) and (iv) the valve chamber + half of the channel (embolus L77).
3. Results and discussion

3.1. Hydrodynamics

A typical simulation without the embolus is shown in Fig. 2. During the opening phase (of Valve 1), when $F$ is applied to Channel 1, the pressure in Channel 1 increases; Valve 1 opens and Valve 2 closes (Fig. 2a and Fig. 2b). Part of the fluid leaves Channel 1 and accumulates in Channel 2, which dilates. During the closing phase (of Valve 1), the force $F$ is applied to Channel 2 and Channel 1 relaxes ($F$ is set to 0). Valve 1 closes while Valve 2 opens (Fig. 2c...
and Fig. 2d). The contraction and, therefore, the force applied to the vein walls accounts for
the level of physical activity of a specific individual. The force used in this study generates a
peak blood velocity around 0.035 m s⁻¹ which corresponds to a low level of physical activity
[13, 14]. This condition was chosen since the risk of DVT increases when the level of
physical activity is low.

The valve opening-closing mechanism in relation to the contraction of the veins around the
valve is confirmed by the available literature [14, 25, 26]. At the time of maximal contraction,
however, the vein assumes an asymmetrical shape shown in Fig. 2d. This is probably due to
the fact that, in our model, the segments of veins (Channel 1 and Channel 2) connecting two
valves are considerably shorter than in reality. The asymmetrical shape can neither be
confirmed nor disproved by available visualization data. This circumstance, however, has
little relevance to our work, which focuses on the dynamics of the valves rather than that of
the veins.
In the next section, we introduce an embolus-like structure both in the main flow (opening region in Fig. 1) and behind the valve (sinus region in Fig. 1). The goal is to show how the presence of a free embolus impacts the flow in the vicinity of the valve.

As mentioned, three parameters are investigated in this case: size, length and flexibility of the aggregate (Table 2).

### 3.2. Embolus displacement in the opening region

Initially, three circular emboli with diameters of $2.6 \times 10^{-3}$ m (Case D26 in Table 2), $5.2 \times 10^{-3}$ m (D52) and $7.8 \times 10^{-3}$ m (D78) are introduced into the flow (Fig. 3a). In the first case (Fig. 3b), the embolus is too small for impacting the flow and crosses the valve with no contact with the leaflets. No significant difference with the pure fluid case is observed.
In the second case (Fig. 3c), although the embolus diameter is bigger than the valve opening, it can cross the valve because of its flexibility and the deformation of the leaflets. The embolus is elastic [15] and recovers its initial shape after the valve. However, contrary to the first case, the flow surrounding the embolus is considerably affected by the presence of the embolus and two vortexes form around the valve.

In the third case (Fig. 3d), the embolus is bigger than the inlet valve chamber and despite the large deformation of both the embolus and the valve, the embolus cannot cross the valve.
Fig. 3. Embolus position and velocity vectors at different times: a) $t = 0$ s for all emboli, b) embolus D26, c) embolus D52, and d) embolus D78.

In reality, the embolus obstruction observed in Fig. 3d would probably resolve itself after a certain time since, normally, the level of physical activity of an individual changes during the day [28], while in our simulation we only considered low physical activity. In our
simulations, a similar situation (i.e. an embolus, initially stuck, crosses the valve after several cycles) occurs when the flexibility of the embolus is higher (Fig. 4).

Fig. 4. Embolus of diameter $7.8 \times 10^{-3}$ m with different elasticity: a) $k_b = 1 \times 10^4$ J m$^{-2}$ (D78) and b) $k_b = 1 \times 10^3$ J m$^{-2}$ (F103).

The vortexes observed in Fig. 3c and Fig. 4 are larger if the length of the embolus is longer as in Fig. 5. In this case, both the flow and the valve behaviour are considerably altered by the presence of the ‘sausage-like’ embolus.
Fig. 5. Velocity magnitude and vectors of the flow and circulation of the embolus (L21) at different times.

3.3. Embolus displacement in the sinus region

In this section, an embolus is located behind Valve 1 (sinus region in Fig. 1). In the medical literature, it is not completely clear where emboli form, but they are often found in the sinus region. After they reach a certain size, they leave the sinus region, and move in the cardiovascular system. In this section, we show how the length of the embolus can affect its permanence in the sinus region. Four emboli with different lengths are simulated (Table 2):
5.9 mm (L6 in Table 2), 19 mm (L19), 37 mm (L37) and 77 mm (L77) and located in the sinus region (Fig. 6a).

Fig. 6b and Fig. 6c show no significant displacement of embolus L6 and embolus L19 after 10 cycles while embolus L37 (Fig. 6d) and L77 (Fig. 6e) show a high displacement. In fact, each embolus interacts with the fluid in a different way. The longer the embolus, the higher the drag force that the liquid exchange with the embolus. This force, however, is not simply proportional to its length, but it also depends on the local velocity at the location of the embolus.

Fig. 6. Embolus position at t = 0 s and t = 28.5 s for a) L6, b) L19, c) L37, d) L77.
In Fig. 7, embolus displacement versus the simulation time indicates that the displacement values oscillate every cycle (forward and backward embolus motion). Embolus L6 never moves and only spins around itself (Fig. 6b) due to its “circular” shape. While embolus L19 begins to move slowly after 20 s. In both cases, the emboli remain in the low flow area (Fig. 8) where the flow velocities are the lowest. On the other extreme, embolus L77 continually moves because the most of the embolus is located in the main flow area (Fig. 8). The displacement of L37 is initially smaller than L77, because a lower fraction is in contact with the high velocity area. However, once it is dragged away from the left end of the sinus it is more easily captured by the main flow due to its smaller size.

Fig. 7. Time evolution of the local displacement for embolus L6, L19, L37, and L77.
4. Conclusions

Free emboli circulation in a valve environment has been studied using the Discrete Multi-
Physics approach. We modelled both fluid and emboli dynamics as well as the leaflets
deformation. In our previous studies [14, 17], an inlet fluid velocity was used to ensure the
blood motion within the rigid channel, while here, the flow is governed by muscle
contractions.

The results show that emboli with a size bigger than the valve can still cross the valve if they
are flexible enough. This observation can be linked with the age of emboli in the body since
the elasticity of an embolus depends on its life-time in the blood system [29], and the older
the embolus the lower its flexibility.

The embolus length plays also a paramount role. In the main flow (opening region), the
embolus can potentially generate new vortex area that can further favour platelets
aggregation. In the low flow (sinus region), the length of the embolus determines how long it takes for the embolus to detach from the sinus region and move within the main flow.

The main conclusion of this work is that the presence of an embolus strongly affects the dynamics of both the fluid and the leaflets in venous valves. Therefore, computer simulations designed to support fundamental research in DVT should account for emboli if they aim at a more realistic description of reality.
