I. INTRODUCTION

Unconventional magnetic orders and phases in frustrated quantum-spin chains appear under a fine balance of the exchange interactions and are sometimes caused by much weaker interactions or fluctuations. A kind of frustration in quasi-one-dimensional (1D) chain magnets is provided by competing interactions, when the intra-chain nearest neighbor (NN) exchange is ferromagnetic \(J_{NN} < 0\) and the next-nearest neighbor (NNN) exchange is antiferromagnetic \(J_{NNN} > 0\). Numerical investigations of frustrated chain magnets within different models\(^6\) have predicted a number of exotic magnetic phases in the magnetization process, such as planar, spiral and different multipolar phases. The theoretical study of the magnetic phase diagram shows that real magnetic phases are very sensitive to interchain interactions and anisotropic interactions.

\(\text{LiCu}_2\text{O}_2\) is a \(S = 1/2\) magnet with frustrated exchange interactions akin to the quantum spin-chain compound \(\text{LiCuVO}_4\).\(^{11,10}\) However, the magnetic structure of \(\text{LiCu}_2\text{O}_2\) appears to be complicated by interchain interactions between coupled chains of magnetic Cu\(^{2+}\) ions. Superexchange interactions via oxygen ions of edge-shared Cu\(\text{O}_4\) squares (see Fig. 1) provide frustration of the intrachain exchange interactions \((J_{NN} < 0, J_{NNN} > 0)\). According to Ref. \(^2\), for the 1D model with the intrachain exchange constants of \(\text{LiCu}_2\text{O}_2\), a chiral long-range order in the low-field range and a quasi-long-range ordered spin-density-wave phase in higher applied magnetic fields \(H\) are expected similar to the above mentioned LiCuVO\(_4\). Experimentally an incommensurate spin structure was observed at \(T < T_N\) in the low-field range, which was ascribed to a planar helical spin structure\(^{4,26}\). Despite the fact that the magnetic properties of \(\text{LiCu}_2\text{O}_2\) and structurally isomorphic \(\text{NaCu}_2\text{O}_2\) have been intensively studied for more than ten years, the magnetic structures of these compounds have not been unambiguously determined. The lack of a reliable interpretation of the magnetic structure makes it impossible to unequivocally explain the nature of the multiferroic properties of \(\text{LiCu}_2\text{O}_2\) and their absence in \(\text{NaCu}_2\text{O}_2\).\(^{24}\)

In the present work, \(^7\)Li NMR spectra of unwinned single crystals of \(\text{LiCu}_2\text{O}_2\) were studied in a magnetic field up to 17 T at temperatures 5-30 K. Field and temperature dependencies of the spectra are discussed in Sec. IV. The evolving magnetic structures were analyzed in the frame of the Dzyaloshinskii-Landau theory of magnetic phase transitions. This analysis was performed in the exchange approximation, i.e., under the assumption that the exchange interactions predominate the interactions of relativistic nature (Sec. V). A theoretical analysis of the relativistic effects, such as anisotropy and electric polarization, is given in Appendix B. From the simulations of the NMR line shape of our observed spectra we elaborate the underlying magnetic structures theoretically and provide a scenario for the case of \(\text{LiCu}_2\text{O}_2\). The structures exhibit an extraordinary configuration: a two-component order parameter characterizes the ordering of the magnetic moments which appear to be not only rotated but also harmonically modulated in size from site to site (Sec. VI). Note that elliptical structures in magnets with a two-component order parameter arise quite
often. However, it is commonly accepted that the ellipticity of the spiral structure is due to relativistic interactions, while the proposed structures for LiCu$_2$O$_2$ are elliptical already in the exchange approximation.

II. CRYSTAL AND MAGNETIC STRUCTURE

LiCu$_2$O$_2$ crystallizes in an orthorhombic lattice (space group $Pnma$) with the unit cell parameters $a$ = 5.73 Å, $b$ = 2.86 Å and $c$ = 12.42 Å. The unit cell parameter $a$ is approximately twice the unit cell parameter $b$. Consequently, LiCu$_2$O$_2$ single crystals, as a rule, exhibit considerable twinning due to the formation of crystallographic domains rotated by 90° around their crystallographically common $c$ axis.

The unit cell of the LiCu$_2$O$_2$ crystal contains four monovalent nonmagnetic cations Cu$^+$ and four divalent cations Cu$_2^{2+}$ with $S=1/2$. The positions of all ions in the crystal lattice are schematically shown in Fig. 1. The unit cell is selected with a dashed line. There are four crystallographically equivalent positions of the magnetic Cu$_2^{2+}$ ions in the crystal unit cell of LiCu$_2$O$_2$, denoted as I, II, III, and IV.

The two-stage transition into a magnetically ordered state occurs at $T_{c1}$ = 24.6 K and $T_{c2}$ = 23.2 K. Neutron scattering and NMR experiments revealed an incommensurate magnetic structure in the magnetically ordered state ($T < T_{c1}$). The wave vector of the incommensurate magnetic structure coincides with the chain direction ($b$-axis). The magnitude of the propagation vector at $T < 17$ K is almost temperature independent and is equal to $0.827 \times 2\pi/b$. The neutron scattering experiments have shown that the adjacent magnetic moments along the $a$-direction are oriented antiparallel, whereas those along the $c$-direction are mutually coaligned. The intra-chain and inter-chain exchange constants were determined from the analysis of the spin wave spectra. The large number of exchange bonds stipulates the ambiguity of the main exchange parameters obtained from Ref. [11]. Theoretical analysis based on local density approach (LDA) and cluster calculations as well as a phenomenological analysis of the temperature dependence of the magnetic susceptibility allow to map the most significant exchange paths. Using the result of these investigations we choose the most suitable set of parameters proposed from neutron experiments: the nearest neighbor exchange interaction is ferromagnetic $J_1 = -7.00$ meV, while the next nearest neighbor exchange interaction is antiferromagnetic $J_2 = 3.75$ meV. The competition between these intra-chain interactions leads to an incommensurate magnetic structure. The antiparallel orientation of magnetic moments of Cu$_2^{2+}$ between nearby chains is caused by strong antiferromagnetic exchange interaction $J_3 = 3.4$ meV. These main exchange paths are shown in Fig. 1. The coupling of the Cu$_2^{2+}$ moments along the $c$ direction and the couplings between the magnetic ions in other crystallographic positions are much weaker. Thus, LiCu$_2$O$_2$ can be considered as a quasi-two dimensional system. The quasi-two-dimensional character of magnetic interactions in LiCu$_2$O$_2$ compound was also proved by resonant soft x-ray magnetic scattering experiments.

The magnetic structure of LiCu$_2$O$_2$ at zero magnetic field was studied by several groups by means of neutron diffraction experiments. The authors of Ref. [12] have proposed the planar spiral spin structure with the spins confined to the $ab$ plane. Polarized neutron scattering measurements have detected the spin component along the $c$ direction, indicating the spiral magnetic structure in the $bc$ plane. The authors of Ref. [24], alternatively, have proposed a spiral spin structure confined to the $(1,1,0)$ plane. It was attempted to extract information about the magnetic structure of LiCu$_2$O$_2$ from
the studies of electric polarization, which accompanies magnetic ordering.\(^23\) Unfortunately, at the moment, the nature of this polarization is not clear\(^21\) and, hence, does not allow to draw an unambiguous conclusion about the zero-field magnetic structure from this type of experiment.

The magnetic structure of LiCu\(_2\)O\(_2\) was also studied by \(^{63,65}\)Cu and \(^7\)Li NMR in Ref.\(^{22}\). The authors of this work describe their results in the frame of planar spin structure and come to the conclusion that the spiral planes do not coincide with any of the crystallographic planes \(ab, ac,\) or \(bc\), respectively.

### III. SAMPLE PREPARATION AND EXPERIMENTAL DETAILS

Untwinned single crystals of LiCu\(_2\)O\(_2\) with the size of several cubic millimeters were prepared by the solution in the melt method as described in Ref.\(^{33}\). The quality of the crystals under investigation was studied in Refs.\(^{34,35}\) and the magnetic properties were found to be identical for all the samples from different batches.

\(^7\)Li nuclei (nuclear spin \(I = 3/2\), gyromagnetic ratio \(\gamma/2\pi = 16.5471\) MHz/T) were probed using pulsed NMR technique. The spectra were obtained by summing fast Fourier transforms (FFT) or integrating the averaged spin-echo signals as the field was swept through the resonance line. NMR spin echoes were obtained using \(\tau_p - \tau_D - \tau_p\) pulse sequences, where the pulse lengths \(\tau_p\) were 1.5 \(\mu s\), the delay times between the pulses \(\tau_D\) were 28 \(\mu s\). Measurements were carried out in the temperature range \(5 \leq T \leq 30\) K stabilized with a precision better than 0.1 K.

### IV. EXPERIMENTAL RESULTS

\(^7\)Li NMR spectra were studied for four orientations of the static magnetic field: \(\mathbf{H} \parallel \mathbf{a}\) (Figs. 2, 3, 4), \(\mathbf{H} \parallel \mathbf{b}\) (Figs. 5 and 10), \(\mathbf{H} \parallel \mathbf{c}\) (Figs. 6, 11, and 12), and \(\mathbf{H} \parallel (\mathbf{c} + 15^\circ)\) (\(\mathbf{H}\) in \(bc\) plane at an angle of \(15^\circ\) with respect to \(c\) axis, Fig. 7).

Figures 2, 5, 6, and 7 show field evolutions of the spectra. The measurements were performed at the lowest temperature 5 K (4.5 K for \(\mathbf{H} \parallel \mathbf{a}\) and \(\nu = 10, 90, 127\) MHz), i.e., well below the magnetic ordering temperature (\(T_N \approx 24\) K). The spectra lines are shifted along the vertical axis for clarity. The resonance field is defined by the vector sum of the external field \(\mathbf{H}\) and the effective field \(\mathbf{H}_{\text{eff}}\) from neighboring magnetic environment. For the case \(H \gg H_{\text{eff}}\) the resonance field \(H_{\text{res}} \approx H + H_{\text{eff}}\), where \(H_{\text{eff}}\) is the projection of the effective field on the direction of the external field. In figs. 2-7, the field scale for each NMR spectrum is shifted by the value of the undisturbed Larmor field \(2\nu/\gamma\) at \(^7\)Li nuclei (\(\gamma/2\pi = 16.5471\) MHz/T). In such a representation, the horizontal axes show \(H_{\text{eff}}\) at the nuclei of nonmagnetic ions.

The magnetic field \(\mathbf{H}_{\text{eff}}\) is defined by the magnetic environment. If the effective field \(H_{\text{eff}}\) varies harmonically in space and the wave length of this variation is incommensurate with the crystal lattice, we expect a broad NMR spectral line where its shape is dominated by two characteristic maxima at the edges. These maxima occur for the case \(\mathbf{H}_{\text{eff}} \parallel \mathbf{H}\) (\(H \gg H_{\text{eff}}\)) and we designate this particular shape as a double-horn pattern.

There are eight chains of Li\(^+\) ions along the \(b\) direction in the magnetic structure of LiCu\(_2\)O\(_2\) with the vector \(\mathbf{q} = (1/2, q, 0)\). All other lithium chains can be obtained by translations. For each of the eight chains

![Figure 2: (color online) Field evolution of \(^7\)Li NMR spectra, \(\mathbf{H} \parallel \mathbf{a}, T = 5\) K (4.5 K for the frequencies 10, 90, 127 MHz, taken from Ref.\(^{22}\)). Low-field phase (black) and high-field phase (colored).](image2.png)

![Figure 3: (color online) Temperature evolution of \(^7\)Li NMR spectra below the spin-reorientation transition, \(\mathbf{H} \parallel \mathbf{a}, \nu = 127\) MHz, \(2\nu/\gamma = 7.68\) T. The spectra are in the paramagnetic (green), intermediate \(T_2 < T < T_1\) (red), and ordered phase \(T < T_{\text{c1}}\) (black), respectively.](image3.png)
we expect a harmonically oscillating effective field generated by the magnetic surrounding. Therefore, in the low-temperature magnetic phase the NMR spectra comprise a superposition of eight double-horn patterns, where some of them may coincide due to symmetry restrictions. All the observed spectra are well described by a sum of not more than four double-horn spectra with nearly the same integral intensity. This fact shows that lithium chains, distanced by the lattice constant \( a \), yield identical NMR spectra.

Figure 2 shows \(^7\)Li NMR field-swept spectra for \( \mathbf{H} \parallel \mathbf{a} \). For the fields below \( \mu_0 H_{c1} \approx 15 \) T all four lithium chains demonstrate identical double-horn shaped lines. This means that the \( a \)-projections of effective fields on \(^7\)Li nuclei oscillate along the lithium chains with the same amplitudes. At higher fields the spectrum transforms into a sum of four double-horn shaped spectra. The value of \( H_{c1} \) agrees with the field of an anomaly in the magnetization curves. The step-like increase of the magnetic susceptibility at this field was previously associated with a spin-flop transition. The value of \( H_{c1} \) is in satisfactory agreement with the value evaluated from ESR in an investigation of the spin-flop transition in LiCuO\(_2\). At fields nearby the phase transition the spectra exhibit hysteric feature: The spectra recorded upon field increase differ from the spectra recorded upon field decrease (Fig. 2, \( 2\pi \nu/\gamma = 15 \) T) which indicates that the phase transition observed at this field is of first order typical for spin-flop transitions.

Figures 3 and 4 show the temperature evolutions of NMR spectra measured around \( (\mu_0 H \approx 7.68 \) T) and \( (\mu_0 H \approx 16.87 \) T), i.e., below and above spin-flop field \( H_{c1} \), respectively. The single line of the paramagnetic phase is significantly broadened in the magnetically ordered phase at \( T_{c1} = (24.8 \pm 0.2) \) and \( (24.3 \pm 0.2) \) K for
spectra measured for the field directions $H$ measurements. Susumably observed in Ref. [36] by dielectric constant measure
d and red colored spectra for the fields up to 9 T was pre
tupled phase. The boundary between phases with blue
and 4. We suggest that they are obtained within spin-
horn spectra. These spectra are red colored in Figs. 3
double-horn spectrum transforms into two (four) double-
decreasing temperature. At temperatures below $T_{c2}$, the
field direction. For $H \parallel b$ a continuous transformation
from two double-horn shaped lines to one double-horn
shaped line is observed upon field increase. For $H \parallel c$
the spectra do not change in the full range of applied magnetic fields as it is documented in Fig. 6. An applied
field direction with small deviation by $15^\circ$ off the
crystallographic $c$-axis yields a duplication of the number
of double-horn pattern towards lower applied magnetic
fields (see Fig. 7). In other words, for this field orienta
tion all four lithium ions show the double-horn spectrum
with individual amplitude of oscillating projection $H_{eff}$. The field splitting decreases with increasing field and dis
appears at elevated fields higher than $(12.5 \pm 0.5)$ T.
Figures 8 and 9 show the field dependencies of the res
onance field values of all edge singularities within the
multi-horn spectral pattern. The fields where the num
ber of edge singularities is halved are 17 and 12.5 T for $H \parallel b$ and $H \parallel (c + 15^\circ)$, respectively, corresponding
to the anomalies observed in the magnetization measure
ments. The fields values of these anomalies were design
ated as $H_{c2}$. Such an anomaly was also observed in the
magnetization measurements for $H \parallel a$ at $\mu_0 H_{c2} \approx 20$ T,
that is out of range of the present experiments. It appears
that we also observed this transition for $H \parallel a$ within the
temperature scan at $\mu_0 H \approx 16.87$ T (see Fig. 4). There,
also the number of edge singularities halves for tempera
tures 15-20 K and the multi-horn shape of the spectra
pattern in this temperature range strongly resembles to
the shapes observed at lowest temperatures for $H > H_{c2}$.

The temperature evolutions of the lithium spectra for $H \parallel b$ and $H \parallel c$ are given in Figs. 10-12. For fields lower
than the critical field $H_{c2}$, the transition from the low
temperature magnetic phase to the paramagnetic phase
occurs through an intermediate phase, with one solitary
double-horn spectral line (see Fig. 11). This intermedi-

FIG. 9: Peak positions of the spectra in Figs. 6 and 7.

7.68 and 16.87 T, respectively. Within a range of 1 K
below $T_{c1}$, the NMR spectrum can be considered as a
superposition of a double-horn spectrum and a paramag
netic solitary line. These spectra are blue colored and ob
served between the temperatures $T_{c1}$ and $T_{c2}$ of the two
step transition into the magnetically ordered phase. The
intensity of the paramagnetic line rapidly decreases with
decreasing temperature. At temperatures below $T_{c2}$, the
double-horn spectrum transforms into two (four) double-
horn spectra. These spectra are red colored in Figs. 3
and 4. We suggest that they are obtained within spin-
flopped phase. The boundary between phases with blue
and red colored spectra for the fields up to 9 T was pre
sumably observed in Ref. [36] by dielectric constant mea
surements.

Figures 5, 6, and 7 show the field evolutions of Li NMR
spectra measured for the field directions $H \parallel b$, $H \parallel c$, and $H \parallel (c + 15^\circ)$, respectively. All spectra were mea
ured at high enough fields, where the normal vector of the
magnetically ordered spin plane appears to follow the field
direction. For $H \parallel b$ a continuous transformation
from two double-horn shaped lines to one double-horn
shaped line is observed upon field increase. For $H \parallel c$
the spectra do not change in the full range of applied magnetic fields as it is documented in Fig. 6. An applied
field direction with small deviation by $15^\circ$ off the
crystallographic $c$-axis yields a duplication of the number
of double-horn pattern towards lower applied magnetic
fields (see Fig. 7). In other words, for this field orienta
tion all four lithium ions show the double-horn spectrum
with individual amplitude of oscillating projection $H_{eff}$. The field splitting decreases with increasing field and dis
appears at elevated fields higher than $(12.5 \pm 0.5)$ T.

FIG. 10: (color online) Temperature evolution of $^7$Li NMR
spectra, $H \parallel b$, $\nu = 248.331$ MHz, and $2\nu/\gamma = 15$ T.
FIG. 11: (color online) Temperature evolution of $^7$Li NMR spectra, $\mathbf{H} \parallel c$, $\nu = 127$ MHz, and $2\pi\nu/\gamma = 7.68$ T.

FIG. 12: (color online) Temperature evolution of $^7$Li NMR spectra, $\mathbf{H} \parallel c$, $\nu = 248.331$ MHz, and $2\pi\nu/\gamma = 15$ T.

ate phase manifests itself within the temperature range between $T_{c1}$ and $T_{c2}$. For elevated fields higher than $H_{c2}$ (Fig. 12), the presence of the intermediate phase is not established. In this case, the single line spectrum of the paramagnetic phase transforms immediately into the characteristic spectral pattern of the low-temperature phase, even within the temperature steps of our measurements. Any intermediate magnetically ordered phase is skipped.

V. THEORY. EXCHANGE APPROXIMATION

The crystal cell of LiCu$_2$O$_2$ contains four magnetic ions Cu$^{2+}$ ($S = 1/2$). At the magnetic transition a doubling of the period along the twofold $C_{2x}$ axis occurs, and as a result eight spiral spin chains appear. Their mutual orientation, amplitudes, phases and possible ellipticity are unknown.

As a first step to interpret the spin structure of LiCu$_2$O$_2$, it is useful to find out the types of the structures with the wave vector $(1/2, q, 0)$ occurring in the Dzyaloshinskii-Landau theory. As it is usually done applying the Landau theory of second-order phase transitions, we assume the region of critical fluctuations to be small, which in our case fits with the experimental observations. In this case, the small value of the spin ($S = 1/2$) is not essential at all, since the quantum fluctuations near the transition are always small in comparison with the thermodynamic ones.

In this section we define a list of such structures – candidates for description of the phase realized in LiCu$_2$O$_2$ at temperatures below $T_{c2}$, as well as within the intermediate phase ($T_{c2} < T < T_{c1}$). It was found that the splitting of the transition is most likely due to small relativistic effects, and that even an additional transition is possible between the temperatures $T_{c1}$ and $T_{c2}$.

The crystal symmetry group of LiCu$_2$O$_2$ – $Pnma$ ($D_{2h}^{16}$) – is defined by the three translations $\tau_a : x \rightarrow x + 1$, $\tau_b : y \rightarrow y + 1$, $\tau_c : z \rightarrow z + 1$, the inversion $I : (x, y, z) \rightarrow (-x, -y, -z)$ and the two screw rotations $C_{2x} : (x, y, z) \rightarrow (x + \frac{1}{2}, -y + \frac{1}{2}, -z + \frac{1}{2})$, $C_{2y} : (x, y, z) \rightarrow (-x, y + \frac{1}{2}, -z)$.

Two-dimensional complex representation corresponding to the wave vector $(1/2, q, 0)$ (compare with the last case considered in Sec. 134 of the book Ref. [37]) is implemented by the functions $\sin \pi x e^{\pm i q y}$, $\cos \pi x e^{\pm i q y}$ (the coordinates $x, y, z$ are measured in the unit cell parameters $a, b, c$, respectively). The functions that transform according to other possible representations associated with this wavevector differ by the factors which are insignificant for constructing the invariants even in the order parameter. For example, there is a representation with a pseudo-scalar factor $\sin 2\pi x \sin 2\pi y \sin 2\pi z$.

The spin density arising at a second-order transition over the considered representation is

$$s(r) = \eta(\sin \pi x (\mu e^{iqy} + \mu^* e^{-iqy}) + \cos \pi y (\nu e^{iqy} + \nu^* e^{-iqy})) f(r),$$

(1)

where $\eta$ is the magnitude of the magnetic order parameter; $\mu, \nu$ are the complex vectors in the spin space, normalized by the condition $\mu\mu^* + \nu\nu^* = 1$; $f(r)$ is a scalar function of coordinates which is invariant with respect to the crystal symmetry group in paramagnetic phase.

To select the exchange effects, we suppose\textsuperscript{38} that the effect of crystalline transformations on the function $s(r)$ is reduced to a corresponding change of coordinates $(x, y, z)$ at a fixed orientation of the spin space. In the Landau
theory of second-order phase transitions, it is convenient to transfer the laws of crystalline transformations from the coordinate functions to the coefficients

\[ I : \mu \rightarrow -\mu^*, \nu \rightarrow \nu^*; \]
\[ C_{2x} : \mu \rightarrow -e^{-i\eta/2}\nu^*, \nu \rightarrow e^{-i\eta/2}\mu^*; \]
\[ C_{2y} : \mu \rightarrow -e^{i\eta/2}\mu, \nu \rightarrow e^{i\eta/2}\nu; \]
\[ \tau_\alpha : \mu \rightarrow -\mu, \nu \rightarrow -\nu; \]
\[ \tau_\beta : \mu \rightarrow e^{i\eta}\mu, \nu \rightarrow e^{i\eta}\nu. \]

For the considered representation, there is the Lifshitz exchange invariant

\[ \mu \partial_3 \nu^* - \nu^* \partial_3 \mu + \mu^* \partial_3 \nu - \nu \partial_3 \mu^*, \] (3)

leading to the instability of the phase transition. Therefore observing a continuous transition over the representation with the wavevector \((1/2, q, 0)\) in LiCu_2O_2 implies that the impact of the invariant \((3)\) in this antiferromagnet is small compared to the anisotropy effects, and we will not take it into account when considering the phases at \(T < T_{2x}\).

In the exchange approximation, the Dzyaloshinskii-Landau expansion of free energy up to the fourth-order terms has the form

\[ F = \tau \eta^2 + \frac{B_0 + B}{2} \eta^4, \] (4)

\[ B = \beta_1(\mu\nu^* + \mu^*\nu)^2 + \beta_2(\mu^*\nu - \nu^*\mu)^2 - \beta_3(\mu\nu^* - \mu^*\nu)^2 + \beta_4(\mu^2 + \nu^2)(\mu^2 + \nu^2) + \beta_5(\mu^2 - \nu^2)(\mu^2 + \nu^2) + 4\beta_6(\mu\nu)(\mu^*\nu^*). \]

Note that in the case of spin-1/2 the fourth order terms of the Landau expansion should be treated as the result of thermodynamic averaging of the microscopic exchange Hamiltonian, which takes into account simultaneous pair permutations of spins belonging to four or more atoms, for example, a biquadratic term of the form \((\sigma_1\sigma_2)(\sigma_3\sigma_4)\), where \(\sigma_i\) is the spin operator of the \(i\)th atom. This peculiarity of the spin-1/2 case was established earlier in the study of the antiferromagnetic phase of crystalline \(^3\)He in Ref. 39.

The real form \(p = \mu\nu^* + \mu^*\nu\) is transformed as the \(z\)-component of the vector, and the real forms \(r = \mu\mu^* - \nu\nu^*, s = i(\mu\nu^* - \mu^*\nu)\) are transformed as components of deformation tensors \(u_{zz}\) and \(u_{zy}\). For the rest spin convolutions we introduce the following notation: \(\zeta = \mu^2 + \nu^2, \omega = \mu^2 - \nu^2, \xi = \mu\nu\).

The free energy \(F\) does not change under the calibration transformation

\[ \mu \rightarrow e^{i\eta}\mu, \nu \rightarrow e^{i\eta}\nu, \] (5)

which corresponds to the incommensurability of arising spin structure to the crystal spacing along the \(y\) axis. Using this invariance, we assume \(\omega\) is real-valued.

The free energy \(F\) is invariant under the replacement \(\mu \rightarrow \nu\), which is connected with the solution transformation under the reflection \(\sigma_x = IC_{2x}\). Taking this into account, we will consider only the solutions with \(\mu \neq 0\).

The free energy \(F\) does not change under the transformation

\[ \nu \rightarrow i\nu, \beta_1 \rightarrow \beta_3, \beta_4 \rightarrow \beta_5. \] (6)

Hence extrema that either remain unchanged or transform into each other under this transformation are possible. Note that the Lifshitz invariant \((3)\) breaks this random symmetry.

Performing the transformation \((9)\) two times we obtain invariance \(F\) under the replacement \(\mu \rightarrow \mu, \nu \rightarrow -\nu\). This invariance is associated with the solution transformation under the crystal rotation \(\tau_\alpha C_{2y}\).

The extra extreme conditions of the free energy \(F\) are

\[ -(B - \beta_2 r)\mu + (\beta_1 p - i\beta_3 s)\nu + (\beta_4 \zeta + \beta_5 \omega)\mu^* + 2\beta_6 \xi \nu^* = 0, \] (7)

\[ (B - \beta_2 r)\nu + (\beta_1 p + i\beta_3 s)\mu + (\beta_4 \zeta - \beta_5 \omega)\nu^* + 2\beta_6 \xi \mu^* = 0. \] (8)

Performing scalar multiplication of the equation \((7)\) by \(\mu^*\) and separating the imaginary part, we find

\[ (\beta_1 - \beta_3)ps + (\beta_4 + \beta_5)\zeta''\omega = 0, \] (9)

where \(\zeta'' = Im(\zeta)\).

Multiplying the equation \((8)\) by \(\nu^*\), for the imaginary part of the product we get

\[ (\beta_1 - \beta_3)ps + (\beta_4 - \beta_5)\zeta''\omega = 0. \] (10)

From the equations \((9)(10)\) it follows that \(ps = \zeta''\omega = 0\). Hence in view of invariance of \((9)\), with \(s \rightarrow p \rightarrow -s\), we can assume that, for example, \(p = 0\). Thus, we have two cases

1) \(p = \zeta'' = 0\), 2) \(p = \omega = 0. \) (11)

At \(\omega = 0\) we can again use the calibration symmetry and choose \(\zeta\) of real-valued. Thus, in all cases it will be \(\zeta'' = 0\).

Performing scalar multiplication of the equation \((7)\) by \(\mu\) and separating the imaginary part at \(p = \zeta'' = 0\), we find

\[ s\xi' = 0. \] (12)

Subtraction of the equation \((7)\) multiplied by \(\nu\), and the equation \((8)\) multiplied by \(\mu\), at \(p = 0\) gives

\[ 2(\beta_2 - \beta_6)\xi - i(-\beta_3 + \beta_4)s\zeta = 0. \] (13)

Hence at \(\zeta'' = 0\) we find \(r\xi' = 0\). Combining this result with the conditions \((11)(12)\) we obtain the following possibilities

1) \(p = \zeta'' = r = s = 0,\)
2) \(p = \zeta'' = \xi' = 0.\) (14)
Let us introduce four real-valued vectors a, b, c, d, such that \( \mu = a + ib \), \( \nu = c + id \). For all possible cases from the general conditions of reality of \( \omega, \zeta \) it follows, that \( \mu^2 \), \( \nu^2 \) are real, which leads to the orthogonality condition \( ab = cd = 0 \).

According to the Appendix A the magnetic structure should be planar and can therefore be written as:

\[
\begin{align*}
\mu &= c_\alpha (lc_\gamma + ik s_\gamma), \\
\nu &= s_\alpha \{c_\nu (lc_\phi + ks_\phi) - is_\phi (ls_\phi - kc_\phi)\},
\end{align*}
\]

where \( l, k \) are mutually orthogonal unit vectors (we use short notation \( c_\alpha = \cos \alpha, \ s_\alpha = \sin \alpha \).

In such parametrization, we have \( p = s_{2\alpha} c_\varphi c_-, \ s = s_{2\alpha} s_\varphi s_+, \ \xi' = s_{2\alpha} c_\varphi c_+ \), and

\[
B = k_1 s_{2\alpha}^2 c_\varphi^2 c_-^2 + 2 k_2 s_{2\alpha}^2 c_\varphi^2 c_+^2 + 3 k_3 s_{2\alpha}^2 s_\varphi^2 s_+^2 + k_4 (c_\varphi^2 c_-^2 - c_\varphi^2 c_+^2)
\]

where \( s_\pm = s_{\gamma \pm \epsilon}, \ c_\pm = c_{\gamma \pm \epsilon} \). At the phase transition a spin structure corresponding to the minimum of \( B \) arises, in this case the maximum of the order parameter takes the maximum value \( \eta = \sqrt{-\tau/(\beta_0 + B)} \). According to [14], we get five scenarios for solving simultaneous equations

\[
\begin{align*}
A) \ c_{2\alpha} &= 0, \ c_\varphi = s_+ = 0; \\
B) \ s_{2\alpha} &= 0, \ c_\varphi = s_- = 0; \\
C) \ s_{2\alpha} &= 0; \\
D) \ s_{2\alpha} &\neq 0, \ c_+ = c_- = 0; \\
E) \ s_{2\alpha} &\neq 0, \ c_\varphi = 0.
\end{align*}
\]

In the framework of these scenarios solving is reduced to elementary minimization of the function \( [16] \) over the remaining free angular parameters in each of them. We find 8 solutions, whose form is independent of the values of \( \beta_i \):

\[
\begin{align*}
A_1: \ \mu &= \frac{1 + ik}{2} , \ \nu = \pm \frac{k + il}{2} , \ B = \beta_0; \\
A_2: \ \mu &= \frac{1}{\sqrt{2}} , \ \nu = \frac{k}{\sqrt{2}} , \ B = \beta_4; \\
B_1: \ \mu &= \frac{1 + ik}{\sqrt{2}} , \ \nu = \pm \frac{1 - ik}{2} , \ B = \beta_0; \\
B_2: \ \mu &= \frac{1}{\sqrt{2}} , \ \nu = i \frac{k}{\sqrt{2}} , \ B = \beta_5; \\
C_1: \ \mu &= 1 , \ \nu = 0 , \ B = \beta_2 + \beta_4 + \beta_5; \\
C_2: \ \mu &= i \frac{1 + ik}{\sqrt{2}} , \ \nu = 0 , \ B = \beta_2; \\
D: \ \mu &= \frac{1}{\sqrt{2}} , \ \nu = \pm \frac{i}{\sqrt{2}} , \ B = \beta_3 + \beta_5 + \beta_6; \\
E: \ \mu &= \frac{1 + ik}{2} , \ \nu = \frac{k - il}{2} , \ B = \beta_3.
\end{align*}
\]

The degeneracy of energy for the solutions \( A_1 \) and \( B_1 \) will be removed if we take into account the next terms of the Dzyaloshinskii-Landau expansion. The solutions \( A_1 \) and \( B_1 \), as well as \( A_2 \) and \( B_2 \) are transformed into each other under the transformation \([16] \). To the list of solutions we obviously need to add two more associated solutions:

\[
\begin{align*}
D^* : \ \mu &= \pm \nu = \frac{1}{\sqrt{2}} , \\
B &= \beta_1 + \beta_4 + \beta_6; \\
E^* : \ \mu &= \pm \nu = \frac{1 + ik}{2} , \\
B &= \beta_1.
\end{align*}
\]

All the phases found can be presented on the phase diagram. Indeed, the value of \( B \) for each solution is obviously an absolute minimum of the function \( B \), if the parameters \( \beta_i \) belonging to it are negative, and the rest of the parameters \( \beta_i \) are positive.

Besides the magnetic structures \([18 \ 19] \) with fixed values of the phase parameters \( \alpha, \gamma, \epsilon \), the symmetry allows the existence of magnetic structures, for which these parameters are functions of the coefficients of energy expansion \( \beta_i \). These solutions may occur in a certain range of values of the parameters \( \beta_i \) only in the scenario \( E \), when \( \varphi = \pi/2 \), see equation \([15] \),

\[
\mu = c_\alpha (lc_\gamma + ik s_\gamma), \ \nu = s_\alpha (c_\nu k - is_\nu 1),
\]

where the parameters \( \alpha, \gamma, \epsilon \) are functions of \( \beta_i \). In this case rather complicated expressions occur, whose form is not necessary to determine the structure realized in \( \text{LiCu}_2\text{O}_2 \) it is enough to have the formulas \([20] \) with three free angles.

As an illustration, let us get the solution in the limit of large values of magnitude of the parameter \( \beta_2 \):

\[
\begin{align*}
\nu^2 &= \frac{\beta_3 + \beta_5}{\beta_4 + \beta_5} < 1, \ c^2 &= \frac{\beta_6 + \beta_5}{\beta_4 + \beta_5} < 1, \\
\frac{e_{2\alpha}}{2} &= \frac{\beta_4 + \beta_5}{\beta_2} c_+ c_- s_+ s_-, \\
B &\approx \beta_3 s_+^2 + \beta_4 c_+^2 + \beta_5 s_-^2 + \beta_6 s_+^2.
\end{align*}
\]

There is also an associate of this solution, corresponding to the transformation \([6] \).

It should be noted that the Lifshitz exchange invariants \([3] \) occur in the phases \( A_2, B_2, E, E^* \), as well as in the set of phases described by \([20] \).

In the presence of magnetic field there is an invariant

\[
H_i H_k (\mu_i \mu_k^* + \mu_k \mu_i^* + \nu_i \nu_k^* + \nu_k \nu_i^*),
\]

giving the anisotropy of the magnetic susceptibility tensor of exchange approximation. For all the structures \([18 \ 19] \) this tensor has obvious axial symmetry. For the
structures described by \(Pnma\) the two main axes of the tensor belong to spin plane.

A spontaneous electric polarization of exchange nature as a quadratic effect in the order parameter (the effect predicted by Indenbom) arises in the phases \(D^*\) and \(E^*\), where the quadratic form \(p\) (transforming as \(z\) component of vector) is not equal to zero.

Exchange striction corresponding to the symmetry breaking \(D_{2h}\) arises in the phases \(C_1, C_2\) (invariant \(ru_{xz}\)) and in the phases \(D, E\) (invariant \(su_{xy}\)).

The relativistic effects are discussed in Appendix B.

VI. DISCUSSION

We discuss the observed NMR spectra using the magnetic phases obtained in Sec. V. The theoretical analysis assumes that in the entire range of fields and temperatures the crystal structure of \(LiCu_2O_2\) is described by the symmetry group \(Pnma\), and the low-temperature magnetic structure is described by the wave vector \((1/2, q, 0)\).

The proposed magnetic phases are obtained under the assumption that the magnetic structure is defined by the dominating exchange interactions, whereas its orientation with respect to the crystal axes is determined by the relativistic interactions with the crystal environment and the applied magnetic field. It was also demonstrated (see Appendix A) that the exchange interactions in \(LiCu_2O_2\) can lead to planar or collinear magnetic structures only. Therefore, non-coplanar magnetic structures will be excluded from further consideration.

In the following we compare the experimental NMR spectra with the simulated ones. We assume that the magnetic moments are localized at the \(Cu^{2+}\) ions. This assumption accounts for the scalar function \(f(r) = \delta(r - R_i)\) in Eq. (1), where \(R_i\) is the radius-vector of \(i\)th \(Cu^{2+}\) ion.

Using Eqs. (1) and (13) the magnetic moment of \(Cu^{2+}\) ion with coordinates \((x, y, z)\) for the coplanar magnetic structure with a wave vector \((1/2, q, 0)\) can be written as follows:

\[
M(x, y, z) = \eta \left \{ \eta_1 \sin(\pi x) \cos(qy + \varphi_{ls}) + \eta_2 \cos(\pi x) \sin(qy + \varphi_{ls}) \right \} + \eta k \left \{ \eta_1 \sin(\pi x) \cos(qy + \varphi_{kc}) + \eta_2 \cos(\pi x) \sin(qy + \varphi_{kc}) \right \}.
\]

(23)

Here, \(l\) and \(k\) are two mutually perpendicular unit vectors, defining the spin plane, and \(\eta\) is the magnitude of the two component magnetic order parameter. The parameters \(\eta_1, \eta_2, \eta_1, \eta_2\) take the values 0 and 1. The angles \(\varphi_{ls}, \varphi_{ls}, \varphi_{kc}, \varphi_{kc}\) denote harmonic phase angles. According to Sec. V there are ten possible magnetic phases \(A_1, A_2, B_1, B_2, C_1, C_2, D, E, D^*, E^*\) with fixed phase parameters. An overview of all values of these parameters is given in Table I.

The letters “C” and “P” in the table mark collinear and planar phases, respectively. The value of the magnetic moment for the collinear phases \(C_1, D, \) and \(D^*\) oscillates harmonically along the chains. The phases \(C_2, E, \) and \(E^*\) are circular. For them, the \(Cu^{2+}\) magnetic moment with constant absolute value rotates by an angle defined by \(q\). Note, the absolute values of magnetic moments differ from chain to neighboring chains within the phases \(C_2\) and \(E^*\). The structures \(A_1, B_1, \) and \(B_2\) can be considered as two embedded elliptical phases with large elliptical axes which are oriented perpendicular with respect to each other between neighboring axes. The planar structure \(A_2\) consists of two embedded collinear structures in which the value of the magnetic moment varies along the chains. In this structure the magnetic moments of neighboring chains are oriented perpendicular with respect to each other. To visualize the structures, we included their sketches in the Table I (the spin plane coincides with the easel plane, \(l\) is horizontal, \(k\) is vertical). The sketches show the ends of the magnetic moment vector for four chains I, II, III, and IV, the arrows indicate the moment rotation direction for the translation along the chain for one of magnetic domains. The magnetic phases which allow magnetically induced electrical polarization (multiferroicity) are marked with the letter “p”.

Besides the structures given by Eqs. (13) and (19), there are the set of structures given by Eq. (20). These structures are described by Eq. (23) with the following values of parameters: \(\varphi_{ls} = \varphi_{ls} = 0, \varphi_{kc} = \varphi_{kc} = \pi/2\). Other parameters are defined by: \(\eta_1 = 2c_\alpha c_\gamma, \eta_2 = 2s_\alpha s_\gamma, \eta_{k1} = 2c_\alpha s_\gamma, \) and \(\eta_{k2} = 2s_\alpha c_\gamma, \) where \(\alpha, \gamma, \) and \(\epsilon\) are arbitrary. The set of structures Eq. (20) contains the phases \(A_1, A_2, D, \) and \(E\) and adjoins to the phases \(C_1\) and \(C_2\).

Concluding the phase description, we note that all suggested magnetic phases are unusual. The values of the magnetic moments of all \(Cu^{2+}\) ions are identical only for the \(E\) phase, for other phases this value oscillates.

Space orientation of the spin structure is defined by the vectors \(l\) and \(k\). For further discussion we suppose that initially the vectors \(l\) and \(k\) are directed along \(a\) and \(b\) crystal axes, respectively. An arbitrary orientation of the spin plane can be obtained by successive rotation of the structure with \(l \parallel a\) and \(k \parallel b\) by an angle \(\Theta_a\) around \(a\) axis, \(\Theta_b\) around \(b\) axis and \(\Theta_c\) around \(c\) axis. The number 1 or 2 or 3 in the brackets after the angle \(\Theta\) specifies the order of the corresponding rotation where it matters. Thus the distribution of the magnetic moments is defined by the four parameters \(\eta, \Theta_a, \Theta_b, \) and \(\Theta_c\) for the structures Eq. (13-19) and by the seven parameters \(\eta, \alpha, \gamma, \epsilon, \Theta_a, \Theta_b, \) and \(\Theta_c\) for the structures Eq. (20). For large enough static fields \((H > H_{c1})\), the spin plane orientation is defined by the field direction, whereas in small fields the orientation is defined by relativistic interactions with the crystallographic environment.

In our spectra simulations we suppose that the effective field on lithium nuclei is defined by the dipolar fields
and the contact Fermi fields. We took into account the dipolar fields from the neighboring moments in the sphere of radius 20 Å and the hyperfine contact fields from the four nearest moments belonging to neighboring chains (Fig. 1). The constants defining the contact fields for three field orientations \( H \parallel a, b, c \) were obtained as follows. First, the shift of \(^7\)Li NMR line at a certain temperature in the paramagnetic state was determined. Then, using the magnetization data from Ref. [36], the magnetic moment of individual \( \text{Cu}^{2+} \) ion at the same temperature and field was calculated. The difference between the computed dipole field at the lithium nuclei and the effective field observed in the experiment was ascribed to the contact field. Thus obtained contact field is in good agreement with the results of Ref. [42]. This value was ascribed to two pairs of the nearest magnetic moments. The first pair is located along \( a \) axis, the second pair is located along \( b \) axis (see Fig. 1). According to the first-principles calculations, the contact field from the first pair is expected to be much larger than the contribution from the second one. It is important that in the magnetically ordered phase the magnetic moments from the first pair are antiparallel; as a result, we can exclude the contact part of effective field in the magnetically ordered phase from further consideration.

We have simulated the spectra for all magnetic structures from Table I and orientations of the applied magnetic field \( H \parallel a, b, c, \) and \((c + 15^\circ)\), respectively. For \( H \parallel a \), the spectral shape does not change with applied magnetic fields up to \( \approx 15 \) T. For higher fields the susceptibility sharply increases, which was interpreted as a spin flop transition. For all other field directions the shape changes with field monotonically. For \( H \parallel b \) and \((c + 15^\circ)\) some pairs of maxima continuously approach each other and merge into one single spectral line at elevated applied fields. This disappearance of the line splitting is accomplished at a field value where anomalies of the magnetic susceptibility were already observed in Ref. [36]. We tried to describe the field evolution of the spectra by changing the spin plane orientation of one individual magnetic phase. A special program was written for spectra simulation. It calculates NMR spectra for the suggested magnetic structures (18,19,20) for given orientations of the static magnetic field with respect to the spin plane. The number of maxima in the spectrum was chosen as the main criterion in order to assess the matching between the observed NMR spectrum and the simulated one. The calculations for all the structures Eqs. (18) and (19) performed with an angular step of 10° showed that the observed field evolution of the spectra for \( H \parallel a \) at the spin-flop field \( H_{c1} \approx 15 \) T the spin plane turns abruptly from the state with \( \Theta_a = 90^\circ, \Theta_b = 0^\circ, \) and \( \Theta_c = 0^\circ \) to the state with \( \Theta_a = 0^\circ, \Theta_b(2) = 90^\circ, \) and \( \Theta_c(1) = 90^\circ \). Figures 13(a) and 13(b) show simulated spectra for \( H < H_{c1} \) and \( H > H_{c1} \), respectively. The best coincidence between ex-

Table I. List of the phases Eqs. (18) and (19), their sketches and parameters in Eqs. (15) and (23).
achieved if one assumes that a phase from the set Eq. (20) is realized. Note here that the inflated value of the magnetic moment used for modeling at $\mathbf{H} \parallel \mathbf{a}$, in comparison with the expected value of $1 \mu_B$, is most probably explained by the contact fields. This additional contribution to the local magnetic field at the $^7$Li nuclear site can be significant for the magnetic field applied in the spin plane.

For $\mathbf{H} \parallel \mathbf{c}$ and $(c+15^\circ)$, respectively, the spectra evolution can be modelled by rotation of the spin plane around the $c$ axis within the structure $A_1$. When $H > H_{c2}$ the spin plane rotation stops. For $\mathbf{H} \parallel \mathbf{c}$, the spectrum exhibits four maxima throughout the entire field range under investigation in this work. Figures 13(e) and 13(f) show simulated spectra for $H < H_{c2}$ and $H > H_{c2}$, respectively. For $\mathbf{H} \parallel (c+15^\circ)$ in the low field range $H < H_{c2}$ the number of maxima becomes equal to four. Figures 13(g) and 13(h) show the simulated spectra for $H < H_{c2}$ and $H > H_{c2}$, respectively.

The orientation of the spin plane with respect to the crystallographic axes for different directions of the applied magnetic field for the phase $A_1$ can be explained by assuming the hierarchy of the anisotropy constants $\lambda_2 > 0, \lambda_1 < 0, |\lambda_4| \ll |\lambda_2| < |\lambda_1|$. For $\mathbf{H} \parallel \mathbf{b}$ we were unable to describe the field evolution of the spectra in the frame of our established structures which we introduce in Eqs. (18) and (19). Figures 13(c) and 13(d) show a possible scenario in the frame of the phases Eq. (20). The low field phase exhibits a similar structure like the phase $A_1$. As the field increases and gets closer to $H_{c2}$, the phase Eq. (20) gradually transforms into the phase $C_1$. Both phases $A_1$ and $C_1$ are located on the boundary of the phases set described by Eq. (20).

Fig. 14 shows the sketches of the structures used in the
proposed scenario.

As a conclusion note, we cannot judge the uniqueness of the proposed scenario of the spectral field evolution within the magnetic structures set by Eq. (20), since the number of free parameters defining these structures is too large.

As the temperature increases, the spectra shape does not change within a scale factor. This indicates that the magnetic structure is not changed until the temperatures approach the transition temperature, and the width of the spectra is determined by the order parameter \( \eta \), see Eq. (23). The transition occurs through an intermediate phase observed in a narrow temperature range \( T_{c2} < T < T_{c1} \). In this temperature range for all field orientations spectra with two characteristic maxima at the edges and a narrow central line ascribed to the paramagnetic state are observed. Relative intensities of these lines change with temperature. As the temperature increases, the intensity of the paramagnetic line increases, while the intensity of the double-horn pattern with the significant maxima at its edges decreases. A phase transition that takes place in two stages by passing through nearby transition temperatures is a characteristic fingerprint of a transition into a planar low-temperature phase in magnetic compounds having easy-axis anisotropy. The observed spectra with such two characteristic maxima are well described by the collinear phase \( D \).

VII. CONCLUSIONS

1. \( ^7 \)Li NMR spectra were measured in applied magnetic fields \( \mu_0 H \) up to 17 T with the temperature range 5-30 K. Four different orientations of the field \( H \parallel a, b, c \), and \( (c + 15^\circ) \) with respect to the crystallographic axes where employed. The field dependent evolution of the spectra was studied in full detail. Anomalies in bulk measurements of the magnetization curves at fields \( H_{c1} \) and \( H_{c2} \), recently reported in the literature, were found to correspond to the fields values where the shape of our NMR spectra changes. At \( H_{c1} \), a first-order phase transition is observed for \( H \parallel a \), which is accompanied by the increase of magnetic susceptibility and most likely indicates a spin-reorientation transition. The observation of the spin-reorientation transition for \( H \parallel a \) supports the model of a planar two-component magnetic structure with the magnetic susceptibility in the field perpendicular to the spin plane larger than that in the field directed within the spin plane. This result is also in agreement with the biaxial character of the magnetic anisotropy suggested in Refs. [25,30]. For other directions of the magnetic field at \( H < H_{c2} \), the shape of the spectra monotonically evolves to a state with less number of maxima upon field increase. At the point where the evolution stops the magnetic susceptibility decreases. Such monotonous field evolution could be explained by the rotation of the spin plane or by monotonous change of magnetic structure. The modeling of our experimental NMR spectra shows that the second scenario is realized.

2. We analyzed the underlying magnetic structures in the frame of Dzyaloshinskii-Landau theory of magnetic phase transitions. A set of possible planar and collinear structures for low temperatures and close to the transition temperature was obtained. Most of these structures have an unusual configuration. They are characterized by a two-component magnetic order parameter and their magnetic moments vary harmonically not only in direction, but also in size. A theoretical analysis made within the exchange approximation, revealed a set of magnetic structures given by Eqs. (18) and (19), which are determined by fixed spin configurations within each individual chain and fixed inter-chain phase relations. Besides these solutions a possibility that the minimum of exchange energy is achieved for a set of magnetic structures described by Eq. (20) was found. For such a case, the configuration of the magnetic structure depends on the values of the coefficients of the energy expansion written in Eq. (4), \( \beta_i \). For these structures, monotonous temperature and field evolutions of the spectra are expected and degeneracy removing occurs due to weak interactions. For such structures, the application of a magnetic field can lead not only to a rotation of the spin plane, but also yields a change into a structure out of the set which we present in Eq. (20).

3. Our simulation of the experimental NMR spectra was performed ab initio from the structures in Eqs. (18), (19), and (20). It has been shown that the experimentally observed spectra for \( H \parallel a, b, c \), and \( (c + 15^\circ) \), respectively, and for temperatures \( T \ll T_N \), and applied fields \( H \ll H_{sat} \) can only be described in the frame of the structures given in Eq. (20). This result allowed us to propose a possible scenario of the magnetic structure evolution which should easily be confirmed by elastic neutron scattering experiments.

VIII. APPENDIX A

Let us write the real and imaginary parts of the equation obtained by scalar multiplication of the equations...
by $\mathbf{e} = [\mathbf{ab}], \mathbf{g} = [\mathbf{cd}]$:

\[
\begin{align*}
(-B + \beta_2 r + \beta_4 \zeta + \beta_5 \omega)\mathbf{ag} &= 0, \\
(-B + \beta_2 r - \beta_4 \zeta - \beta_5 \omega)\mathbf{bg} &= 0, \\
(\beta_1 p + 2 \beta_6 \xi')\mathbf{ag} + (2 \beta_6 \xi'' - \beta_3 s)\mathbf{bg} &= 0, \\
(2 \beta_6 \xi'' + \beta_3 s)\mathbf{ag} + (\beta_1 p - 2 \beta_6 \xi')\mathbf{bg} &= 0, \\
(-B - \beta_2 r + \beta_4 \zeta - \beta_5 \omega)e\mathbf{ce} &= 0, \\
(-B - \beta_2 r - \beta_4 \zeta + \beta_5 \omega)e\mathbf{de} &= 0, \\
(\beta_1 p + 2 \beta_6 \xi')\mathbf{ce} + (2 \beta_6 \xi'' + \beta_3 s)\mathbf{de} &= 0, \\
(2 \beta_6 \xi'' - \beta_3 s)\mathbf{ce} + (\beta_1 p - 2 \beta_6 \xi')\mathbf{de} &= 0.
\end{align*}
\] (24)

These simultaneous equations lead to four types of solutions (accurate within the above mentioned transformations $\mu \rightarrow \nu, \mu \rightarrow i \mu$):

I. If $\mathbf{ag} = \mathbf{bg} = 0$, then the vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}, \mathbf{d}$ are coplanar and therefor $\mathbf{ce} = \mathbf{de} = 0$. These structures were considered above.

II. If $\mathbf{ag} = \mathbf{ce} = 0$, $\mathbf{bg}, \mathbf{de} \neq 0$, i.e. when simultaneously three vectors $\mathbf{a}, \mathbf{c}, \mathbf{d}$ are coplanar and three vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are coplanar, this is possible only at $\mathbf{a}|\mathbf{c}$ Then $p = s = \xi = 0, \beta_2 r = -\beta_5 \omega$, and $B = -\beta_4 \zeta$.

III. If $\mathbf{ce} = 0, \mathbf{ag}, \mathbf{bg}, \mathbf{de} \neq 0$, then

\[
\begin{align*}
\beta_1^2 p^2 + \beta_3^2 s^2 &= 4 \beta_6^2 \xi' \xi^* \\
B &= \beta_2 r = -\beta_4 \zeta = \beta_5 \omega.
\end{align*}
\]

IV. If $\mathbf{ag}, \mathbf{bg}, \mathbf{ce}, \mathbf{de} \neq 0$, then $r = \zeta = \omega = B = 0, \beta_1^2 p^2 + \beta_3^2 s^2 = 4 \beta_6^2 \xi'^2$.

Thus, the possibility of existence analysis for non-coplanar structures is reduced to the analysis of $2 \times 3 = 6$ cases. Here the same solution can be obtained repeatedly, but no one solution will be missed.

Let us introduce two orthonormal bases in the spin space $\mathbf{I}, \mathbf{k}, \mathbf{n}$ and $\mathbf{l}, \mathbf{k}, \mathbf{n}$, and the parameters $\alpha, \gamma, \epsilon, \zeta$ such that

\[
\begin{align*}
\mathbf{a} &= \mathbf{l}_\alpha \mathbf{c}_\gamma, \\
\mathbf{b} &= \mathbf{k}_\alpha \mathbf{s}_\gamma,
\end{align*}
\]

\[
\begin{align*}
\mathbf{c} &= \mathbf{l}_\alpha \mathbf{s}_\gamma, \\
\mathbf{d} &= \mathbf{k}_\alpha \mathbf{s}_\gamma.
\end{align*}
\]

Let us introduce Euler angles $\theta, \varphi, \psi$, to specify the mutual orientation of the spin bases:

\[
\begin{align*}
\mathbf{I} &= \mathbf{l}_\alpha \mathbf{c}_\gamma - \sqrt{1 - \cos^2 \theta} \mathbf{c}_\theta \mathbf{s}_\varphi + \sqrt{1 - \cos^2 \theta} \mathbf{s}_\theta \mathbf{c}_\varphi, \\
\mathbf{k} &= \mathbf{l}_\epsilon \mathbf{s}_\varphi - \sqrt{1 - \cos^2 \epsilon} \mathbf{s}_\epsilon \mathbf{c}_\theta + \sqrt{1 - \cos^2 \epsilon} \mathbf{c}_\epsilon \mathbf{c}_\varphi, \\
\mathbf{n} &= \mathbf{l}_\zeta \mathbf{s}_\psi - \sqrt{1 - \cos^2 \zeta} \mathbf{s}_\zeta \mathbf{c}_\theta + \sqrt{1 - \cos^2 \zeta} \mathbf{c}_\zeta \mathbf{c}_\psi,
\end{align*}
\]

II. From the condition $\mathbf{a}|\mathbf{c}$ it follows, that

\[
\mu = c_\alpha (l_\alpha c_\gamma + i k_\alpha s_\gamma), \quad \nu = s_\alpha (c_\epsilon l_\epsilon + i s_\epsilon (k_\alpha c_\theta + n_\epsilon))
\]

In this case, the condition $s = 0$ is performed automatically. The condition $p = \xi = 0$ for the considered non-coplanar structures $(c_\alpha s_\alpha \neq 0)$ is reduced to the relation $c_\gamma c_\epsilon = s_\gamma s_\epsilon 0$. Hence for non-coplanar structures we have either $c_\gamma = c_\theta = 0$, or $c_\epsilon = c_\theta = 0$. In the first case

\[
\mu = ic_\alpha k_\epsilon, \quad \nu = s_\alpha (c_\epsilon l_\epsilon + i s_\epsilon n_\epsilon), \\
B = \beta_2 c_\alpha^2 l_\epsilon + \beta_4 (s_\alpha^2 c_\epsilon^2 - c_\alpha^2) + \beta_5 (s_\alpha^2 c_\epsilon^2 + c_\alpha^2)^2.
\]

It is easy to verify that there are no non-coplanar solutions here. The same result is obtained in the case of $c_\epsilon = c_\phi = 0$.

III. From the condition $\mathbf{ce} = 0$ for non-coplanar structures it follows that $s_\gamma c_\epsilon = 0$.

III A. If $s_\zeta = 0$, then

\[
\mu = c_\alpha (l_\alpha c_\gamma + i k_\alpha s_\gamma), \\
\nu = s_\alpha (c_\epsilon l_\epsilon + i s_\epsilon (k_\alpha c_\theta + n_\alpha)).
\]

From the general for 1a,b condition $p = 0$ we found, that either $c_\epsilon = 0$, and then $a|\epsilon$, i.e. we return to the already considered type of solution II, or

\[
c_\gamma c_\epsilon = -s_\gamma s_\epsilon c_\theta.
\]

In the case 1a) we have $r = 0$, whence it follows, that $c_{2\alpha} = 0$, i.e.

\[
\mu = \frac{l_\alpha c_\epsilon + i k_\epsilon s_\gamma}{\sqrt{2}}, \\
\nu = \frac{c_\alpha (l_\epsilon c_\varphi + k_\epsilon s_\varphi) + i s_\epsilon (c_\theta c_\varphi - k_\theta c_\varphi + n_\theta)}{\sqrt{2}}.
\]

and, according to III, $\zeta = \omega = 0$. Hence we found $c_{2\gamma} = c_{2\varphi} = 0$, i.e., according to 24, $c_\theta = \cot \gamma \cot \epsilon = \pm 1$, i.e. we return to coplanar structure again.

In the case 1b) from the condition $\xi' = 0$ we find

\[
c_\gamma c_\epsilon = s_\gamma s_\epsilon c_\theta.
\]

For non-coplanar structure $s_\alpha \neq 0$, and from the equations 25, it follows, that $c_\gamma c_\epsilon = s_\gamma s_\epsilon 0$. Hence there are three options of solution:

1. $c_\gamma = c_\theta = 0 : \mu = ic_\alpha k_\epsilon, \nu = s_\alpha (c_\epsilon l_\epsilon + i s_\epsilon (k_\alpha c_\theta + n_\alpha))$,

2. $c_\gamma = c_\epsilon = 0 : \mu = c_\alpha l_\epsilon, \nu = i s_\alpha (c_\epsilon l_\epsilon - k_\epsilon c_\theta + n_\epsilon)$,

3. $c_\epsilon = c_\theta = 0 : \nu = ic_\alpha k_\alpha, \mu = c_\alpha (l_\alpha c_\gamma + i k_\alpha s_\gamma)$,

\[
B = \beta_2 c_\alpha^2 + \beta_5 (c_\alpha^2 c_\epsilon^2 + c_\alpha^2),
\]

\[
3 c_\epsilon = c_\theta = 0 : \nu = ic_\alpha k_\alpha, \mu = c_\alpha (l_\alpha c_\gamma + i k_\alpha s_\gamma),
\]

\[
B = \beta_2 c_\alpha^2 + \beta_5 (c_\alpha^2 c_\epsilon^2 + c_\alpha^2),
\]

It is easy to verify that in these three options only coplanar structures appear.

\[
\begin{align*}
\mathbf{g} &= [\mathbf{cd}], \\
\mathbf{e} &= [\mathbf{ab}], \\
(l_\alpha c_\gamma + i k_\alpha s_\gamma)
\end{align*}
\]
IIIB. If \( c_z = 0 \), then the vector \( c = 0 \). Let us direct \( \mathbf{n} \) along the vector \( \mathbf{d} \), then
\[
\mu = c_\alpha (c_\alpha \mathbf{l} + i s_\gamma \mathbf{k}),
\]
\[
\nu = is_\alpha (ls_\theta s_\varphi - ks_\varphi c_\varphi + nc_\theta),
\]
\[
\mathcal{B} = (\beta_1 + \beta_3)c_{\alpha}^2 s_\varphi^2 s_\theta^2 - (\beta_3 + \beta_6)c_{\alpha}^2 s_{2\alpha} s_\varphi^2 + \beta_2 c_{2\alpha} + \beta_4 (c_{\alpha}^2 c_{2\gamma} - s_{2\alpha}^2)^2 + \beta_5 (c_{\alpha}^2 c_{2\gamma} + s_{2\alpha}^2)^2.
\]
Here also only coplanar structures appear.

IV. From the condition \( r = \zeta = \omega = p = 0 \) it follows, that \( \alpha = \gamma = \epsilon = \pi/4; \psi + \varphi = \pi/2 \). Thus, \( 2\mu = 1 + ik \) and
\[
2\nu = ls_\varphi c_\varphi (1 - c_\theta) + k (s_\varphi^2 + c_\varphi^2) + nc_\varphi s_\theta,
\]
\[
+i \{ -l (c_\varphi^2 + c_\varphi^2) + ks_\varphi c_\varphi (c_\theta - 1) + ns_\varphi s_\theta, \}
\]
\[
\mathcal{B} = \frac{\beta_3}{4} (1 + c_\theta)^2 + \frac{\beta_6}{4} (1 - c_\theta)^2.
\]
Minimizing the function \( \mathcal{B} \), we found
\[
c_\theta = \frac{\beta_6 - \beta_3}{\beta_6 + \beta_3}, \quad \mathcal{B} = \frac{\beta_3 \beta_6}{\beta_3 + \beta_6}.
\]
We see, that the condition \( \mathcal{B} = 0 \), as it should be for the solutions type IV, is only performed when \( \beta_3 = \beta_6 \) equals to zero.

Thus, there are no extrema of the function \( \mathcal{B} \), corresponding to non-coplanar structures.

IX. APPENDIX B

Relativistic effects. To obtain relativistic invariants the action of rotational elements, in contrast to the exchange symmetry transformations \([2]\), has to be extended to the spin indices
\[
C_{2x} : \mu_x \rightarrow -e^{-i\theta/2} \nu_x^*, \quad \nu_{y,z} \rightarrow e^{-i\theta/2} \nu_{y,z};
\]
\[
\nu_x \rightarrow -e^{-i\theta/2} \mu_x^*, \quad \nu_{y,z} \rightarrow -e^{-i\theta/2} \nu_{y,z};
\]
\[
C_{2y} : \mu_y \rightarrow -e^{i\theta/2} \mu_y, \quad \mu_{x,z} \rightarrow e^{i\theta/2} \mu_{x,z},
\]
\[
\nu_y \rightarrow e^{i\theta/2} \nu_y, \quad \nu_{x,z} \rightarrow -e^{i\theta/2} \nu_{x,z}.
\]
(27)

Anisotropy energy in general case has the form
\[
\lambda_1 (\mu_x \mu_x^* + \nu_x \nu_x^*) + \lambda_2 (\mu_y \mu_y^* + \nu_y \nu_y^*) + \lambda_3 (\mu_z \mu_z^* + \nu_z \nu_z^*) + \lambda_4 (\mu_x \mu_y^* + \mu_y \mu_x^* + \nu_x \nu_y^* + \nu_y \nu_x^*) + \lambda_5 (\mu_x \nu_y - \mu_y \nu_x + \nu_x \mu_y - \nu_y \mu_x),
\]
(28)

Let us give the expressions for the anisotropy energy of the phases:
\[
A_1 : -\frac{\lambda_1}{2} \nu_x^2 - \frac{\lambda_2}{2} \nu_y^2 \pm \lambda_4 (l_x l_y - k_x k_y);
\]
\[
A_2 : -\frac{\lambda_1}{2} \nu_x^2 - \frac{\lambda_2}{2} \nu_y^2 + \lambda_3 (l_x l_z + k_x k_z);
\]
\[
B_1 : -\frac{\lambda_1}{2} \nu_x^2 - \frac{\lambda_2}{2} \nu_y^2 \pm \lambda_4 (l_x k_y + k_x l_y);
\]
\[
B_2 : -\frac{\lambda_1}{2} \nu_x^2 - \frac{\lambda_2}{2} \nu_y^2 + \lambda_3 (l_y l_z - k_y k_z) + \pm \lambda_4 (l_y k_z + k_y l_z);
\]
\[
C_1 : \frac{\lambda_1}{2} l_x^2 + \frac{\lambda_2}{2} l_y^2 + 2 \lambda_3 l_x l_z;
\]
\[
C_2 : -\frac{\lambda_1}{2} l_x^2 - \frac{\lambda_2}{2} l_y^2 + \lambda_4 n_x n_z;
\]
\[
D : \frac{\lambda_1}{2} l_x^2 + \frac{\lambda_2}{2} l_y^2 + 2 \lambda_3 l_y l_z;
\]
\[
E : -\frac{\lambda_1}{2} l_x^2 - \frac{\lambda_2}{2} l_y^2 \pm \lambda_4 n_x n_y;
\]
\[
D^* : \frac{\lambda_1}{2} l_x^2 + \frac{\lambda_2}{2} l_y^2;
\]
\[
E^* : -\frac{\lambda_1}{2} l_x^2 - \frac{\lambda_2}{2} l_y^2.
\]

Here for the planar structures we introduced the normal vector to the spin plane \( n = [lk] \) and used the relation
\[
l_x l_\beta + k_\alpha k_\beta + n_\alpha n_\beta = \delta_{\alpha\beta}.
\]

Electric polarization of relativistic nature is due to the following invariants:
\[
-d_1 E_y (\mu_x \nu_z^* + \mu_z \nu_x^* + \mu_z \nu_x^* + \mu_x \nu_z^*) - d_2 E_y (\mu_y \nu_z^* + \mu_z \nu_y^* + \mu_z \nu_y^* + \mu_y \nu_z^*) - d_3 E_z (\mu_x \nu_z^* + \mu_z \nu_x^*).
\]
(29)

Accordingly, in five phases of twelve components of polarization \( P_x, P_y, P_z \) occur:
\[
A_1 d_1 (l_x k_z + k_z l_x), d_2 (l_y k_z + k_y l_z), d_3 l_z k_z;
\]
\[
A_2 d_1 (l_x k_z + k_z l_x), d_2 (l_y k_z + k_y l_z), d_3 l_z k_z;
\]
\[
B_1 d_1 (l_x l_z - k_z k_x), d_2 (l_y l_z - k_y k_z), d_3 (l_z^2 - k_z^2);
\]
\[
D^* 2d_1 l_x l_z, 2d_2 l_x l_z, P_0 + d_3 l_z^2;
\]
\[
E^* d_1 (l_x l_z + k_z k_x), d_2 (l_y l_z + k_y k_z), P_0 - d_3 l_z^2.
\]

Here for the phases \( D^* \) \( E^* \) we added the already mentioned polarization of exchange nature \( P_0 \). Note that \( P_0 \) and the relativistic contribution to the polarization, as well as the "anomalous" terms of anisotropy \( \lambda_3, \lambda_4 \) are given for the one of four possible domains, differed by the sign of \( \nu \) and the replacement \( \mu \to \nu \).

Thus, if we exclude the collinear structure \( D^* \), there are four candidates for the phase, observed in LiCu2O2 at the temperature \( T < 23, 2K \).

Due to the low symmetry of the crystal, there are too many invariants caused by the relativistic effects of magnetostriction: \( \eta_{xx} u_{xx}, \eta_{xx} u_{yy}, \eta_{yy} u_{xx}, \eta_{yy} u_{yy}, \eta_{xy} u_{xy}, \eta_{yx} u_{yx}, \eta_{xy} u_{yx}, \eta_{yx} u_{xy}, \eta_{yz} u_{yz}, \eta_{zy} u_{zy}, \eta_{zr} u_{zr}, \eta_{rz} u_{rz}, \eta_{yz} u_{yz}, \eta_{zy} u_{zy}, \eta_{zr} u_{zr}, \eta_{rz} u_{rz}. \)
Therefore the use of strain measurements for the task of structure selection is difficult.

**Spin-orbit splitting of phase transition.** The above regular accounting for relativistic effects under the perturbation theory may become inapplicable in the vicinity of the transition, where their contribution necessarily becomes comparable to the exchange quadratic term of the Dzyaloshinskii-Landau expansion \( r \eta^2 \). In this case, an intermediate magnetic phase may appear in a small vicinity of the transition in the case, when active representation of the exchange approximation is not one-dimensional. Let us find out the features of this phase, suggesting the Lifshitz instability is weak.

Let us select the real and imaginary parts in the order parameter \( \eta \mu = a + ib, \eta \nu = c + id \), without imposing any restrictions on the real-valued vectors \( a, b, c, d \). In these variables the quadratic part of the Dzyaloshinskii-Landau expansion has the form

\[
\begin{aligned}
(\tau + \lambda_1)(a_x^2 + b_x^2 + c_x^2 + d_x^2) + \\
(\tau + \lambda_2)(a_y^2 + b_y^2 + c_y^2 + d_y^2) + \\
\tau(a_x^2 + b_x^2 + c_x^2 + d_x^2) + \\
2\lambda_2(a_x a_y + b_x b_y - c_x c_y - d_x d_y) + \\
2\lambda_2(a_x d_y - b_x c_y + d_x a_y - c_x b_y). \\
\end{aligned}
\]

In the immediate vicinity of the transition we can not neglect the Lifshitz invariant \( 3 \), and should also consider suppressive instability quadratic in the gradients exchange invariant

\[
\mathcal{L}(ac' - ca' + bd' - db') + \\
+ g(a'^2 + b'^2 + c'^2 + d'^2),
\]

where prime means differentiation with respect to coordinate \( x \).

In the general case this is rather complicated task. However, in LiCuO\(_{2}\) according to the experimental data \( 36 \) if the parameter \( \lambda_1 \) is negative and substantially exceeds the value of the remaining anisotropy constants, then the analysis of the transition is much easier. The transition then should occur at \( \tau \approx -\lambda_1 \) and we may neglect \( y \) and \( z \) components of the vectors in the vicinity of \( T_{c1} \). As a result, the quadratic term in the Dzyaloshinskii-Landau expansion in the order parameter has the form

\[
F_2 = \tau \eta^2 + \mathcal{L}(ac' - ca' + bd' - db') + \\
+ g(a'^2 + b'^2 + c'^2 + d'^2),
\]

where \( \eta^2 = a^2 + b^2 + c^2 + d^2 \), the same for all vectors index \( x \) has been omitted.

Let us turn to the Fourier components \( a = a_k e^{ikx} + a_k^* e^{-ikx}, ..., k > 0 \). For the contribution of single harmonic we have

\[
F_2 = (\tau + gk^2)(a_k^* a_k + b_k^* b_k + c_k^* c_k + d_k^* d_k) + \\
+ ik\mathcal{L}(a_k^* c_k - b_k^* b_k + b_k^* d_k - d_k^* c_k).
\]

For given magnitude \( a_k^* a_k + b_k^* b_k + c_k^* c_k + d_k^* d_k \) and wavevector this contribution is minimal if

\[
c_k = ia_k, d_k = ib_k,
\]

then

\[
F_2 = 2(\tau - \mathcal{L}k + gk^2)(a_k^* a_k + b_k^* b_k).
\]

The phase transition occurs when the temperature decreases and the minimal value of the coefficient in \( 35 \) changes sign at \( k = k_0 = \mathcal{L}/2g \). The relative phase and amplitude of the components \( a_k \) and \( b_k \) are determined by the minimum condition of the function

\[
B = 4\beta_1(ac + bd)^2 + \\
\beta_2(a^2 + b^2 - c^2 - d^2)^2 + 4\beta_3(ad - bc)^2 + \\
\beta_4[(a^2 - b^2 + c^2 - d^2)^2 + 4(ab + cd)^2] + \\
\beta_5[(a^2 - b^2 - c^2 + d^2)^2 + 4(ab - cd)^2] + \\
4\beta_6(a^2 b^2 + a^2 d^2 + b^2 c^2 + b^2 d^2)^2
\]

at the fixed magnitude \( \eta^2 = 2(a_k^* a_k + b_k^* b_k) \) and fulfillment the condition \( 34 \).

Turning to the Fourier components in the expression \( 36 \) and integrating over the volume we get

\[
8(\beta_1 + \beta_2)(a^2 + b^2)(a^2 b^2 + b^2 a^2 - 16\beta_3(a^* b - ab^*)^2 \\
+ 16\beta_4(a^2 a^2 + a^2 b^2 + b^2 a^2 + a^2 b^2)^2 \\
+ 8(\beta_5 + \beta_6)(a^2 - b^2)(a^2 - b^2) + 4aa^* bb^*)
\]

here the indices \( k \) have been omitted. Introducing parametrization

\[
a_k = \frac{n}{2} e^{-i\varphi} s_x \delta, \quad b_k = \frac{n}{2} e^{i\varphi} e^{i(\delta - \varphi)},
\]

we get

\[
B = B_0 + A^2 s_x^2 s_y^2,
\]

where

\[
B_0 = \frac{1}{2} (\beta_1 + \beta_2 + 2\beta_4 + \beta_5 + \beta_6), \\
A = -\frac{1}{2} (\beta_1 + \beta_2 + 2\beta_3 + 2\beta_4 + \beta_5 + \beta_6).
\]
If $A < 0$ then the minimum $B$ occurs at $\phi = \pi/4$, $\delta = \pi/2$. If $A > 0$ then there are two solutions 1) $\phi = 0$ (or $\phi = \pi/2$), and the value of $\delta$ is not relevant, and 2) $\delta = 0, \pi$. Thus, the following solutions are the candidates for the intermediate phase

$$I_1 : \mu_x = \pm i \nu_x = \frac{e^{-i(kx - \varphi)}}{\sqrt{2}}$$

$$I_2 : \mu_x = \cos(kx - \varphi), \nu_x = \pm \sin(kx - \varphi);$$

$$I_3 : \mu_x = \cos(kx - \varphi), \nu_x = \pm i \sin(kx - \varphi).$$

Let us note that there are no associated solutions transforming into each other under the transformation here, since, as noted above, the Lifshitz invariant breaks this random symmetry. One of these phases has to be realized at the transition point $T_{c1}$. Note that only in the phase $I_2$ electric polarization of exchange nature occurs.

There are two possible scenarios with decreasing temperature: either a first-order transition into one of the phases considered above at the temperature $T_{c2}$ or, if the low-temperature phase is noncollinear, then a first-order transition into another intermediate collinear phase $C_1, D$ or $D^*$ is possible.

† Electronic address: svistov@kapitza.ras.ru

Since redundant solutions may occur at deriving (17), all the solutions must be checked by direct substitution into the original equations.

We tried to fit the experimental spectra in the model where the second pair of copper ions induces the dominant contact field. This assumption does not change the conclusions of our paper.

The program can be found at http://www.kapitza.ras.ru/rgroups/esrgroup/numa.html.
