Measurement of the time-integrated $CP$ asymmetry in $D^0 \to K_S^0 K_S^0$ decays

The LHCb collaboration

E-mail: giulia.tuci@pi.infn.it

ABSTRACT: A measurement of the time-integrated $CP$ asymmetry in $D^0 \to K^0_S K^0_S$ decays is reported. The data correspond to an integrated luminosity of about 2 fb$^{-1}$ collected in 2015–2016 by the LHCb collaboration in $pp$ collisions at a centre-of-mass energy of 13 TeV. The $D^0$ candidate is required to originate from a $D^{\ast+} \to D^0 \pi^+$ decay, allowing the determination of the flavour of the $D^0$ meson using the pion charge. The $D^0 \to K^+ K^-$ decay, which has a well measured $CP$ asymmetry, is used as a calibration channel. The $CP$ asymmetry for $D^0 \to K^0_S K^0_S$ is measured to be

$$A^{CP}(D^0 \to K^0_S K^0_S) = (4.3 \pm 3.4 \pm 1.0)\%,$$

where the first uncertainty is statistical and the second is systematic. This result is combined with the previous LHCb measurement at lower centre-of-mass energies to obtain

$$A^{CP}(D^0 \to K^0_S K^0_S) = (2.3 \pm 2.8 \pm 0.9)\%.$$

1 Introduction

In the Standard Model, violation of charge-parity (CP) symmetry originates from the presence of a single phase in the Cabibbo-Kobayashi-Maskawa (CKM) matrix [1]. Experimental results support the CKM mechanism for CP violation, but additional sources of CP violation are needed to explain cosmological observations of the relative abundance of matter and antimatter in the universe [2]. In the charm sector, CP violation has not yet been observed, but measurements of CP asymmetries in Cabibbo-suppressed $D^0 \to h^+ h^−$ decays ($h = \pi, K$) have reached 0.2% and 0.03% precision for time-integrated [3] and indirect CP asymmetries [4], respectively.

The $D^0 \to K_s^0 K_s^0$ decay is a promising discovery channel for CP violation in charm decays [5]. Only loop-suppressed amplitudes and exchange diagrams that vanish in the SU(3) flavour limit contribute to this decay. These amplitudes can have different strong and weak phases and are of similar size. The time-integrated CP asymmetry, $A^{CP}$, in $D^0 \to K_s^0 K_s^0$ decays may therefore be enhanced to an observable level [6], and could be as large as 1.1% [5]. Examples of such diagrams are shown in figure 1. The most precise measurement of this asymmetry to date, $A^{CP}(K_s^0 K_s^0) = (−0.02 \pm 1.53 \pm 0.17)\%$, has been performed by the Belle collaboration [7]. Earlier measurements were also performed by the LHCb [8] and CLEO [9] collaborations. This article reports a new measurement of $A^{CP}$ in the decay $D^0 \to K_s^0 K_s^0$ using LHCb data collected in 2015 and 2016.

The measurement of the CP asymmetry, defined as

$$A^{CP}(K_s^0 K_s^0) = \frac{\Gamma(D^0 \to K_s^0 K_s^0) − \Gamma(D^0 \to K_s^0 K_s^0)}{\Gamma(D^0 \to K_s^0 K_s^0) + \Gamma(D^0 \to K_s^0 K_s^0)}.$$

Figure 1. Exchange (left) and penguin annihilation (right) diagrams contributing to the $D^0 \to K^0_S K^0_S$ amplitude. Based on ref. [5].

requires knowledge of the flavour of the $D^0$ meson at production. A sample of flavour-tagged $D^0 \to K^0_S K^0_S$ decays is obtained by selecting $D^{*+}$ mesons that are produced in the primary interaction (hereafter referred to as prompt), with the subsequent decay $D^{*+} \to D^0 \pi^+$. The charge of the pion in this decay identifies the flavour of the accompanying $D^0$ meson. The effect of $D^0 - \bar{D}^0$ mixing [10] is negligible compared to the precision of this analysis and is not considered further.

The experimentally measured quantity is the raw asymmetry, defined as

$$A_{\text{raw}} = \frac{N_{D^0} - N_{\bar{D}^0}}{N_{D^0} + N_{\bar{D}^0}},$$

(1.2)

where $N_{D^0}$ is the measured yield of $D^{*+} \to D^0 \pi^+$, $D^0 \to K^0_S K^0_S$ decays and $N_{\bar{D}^0}$ is the measured yield of $D^{*-} \to \bar{D}_s^0 \pi^-$, $\bar{D}^0 \to K^0_S K^0_S$ decays. This observable is related to the $CP$ asymmetry by the expression, valid for small asymmetries,

$$A_{\text{raw}} \approx A_{\text{CP}} + A_{\text{prod}} + A_{\text{det}},$$

(1.3)

where $A_{\text{prod}}$ is the $D^{*\pm}$ production asymmetry, defined as $A_{\text{prod}} = \frac{\sigma(D^{*+}) - \sigma(D^{*-})}{\sigma(D^{*+}) + \sigma(D^{*-})}$, and $A_{\text{det}}$ is the $\pi^\pm_{\text{tag}}$ detection asymmetry, defined as $A_{\text{det}} = \frac{\epsilon(\pi^+_\text{tag}) - \epsilon(\pi^-_{\text{tag}})}{\epsilon(\pi^+_\text{tag}) + \epsilon(\pi^-_{\text{tag}})}$. The symbol $\pi^\pm_{\text{tag}}$ refers to the pion in the $D^{*\pm}$ decay. To a very good approximation, knowledge of $A_{\text{det}}$ and $A_{\text{prod}}$ is unnecessary when using a calibration channel with the same production and tagging mechanism. The decay channel $D^0 \to K^+ K^-$ is used for this purpose. The production and detection asymmetries cancel when taking the difference of the raw asymmetries:

$$\Delta A_{\text{CP}} = A_{\text{raw}}(K^0_S K^0_S) - A_{\text{raw}}(K^+ K^-)$$

$$= A_{\text{CP}}(K^0_S K^0_S) - A_{\text{CP}}(K^+ K^-).$$

(1.4)

(1.5)

The quantity $A_{\text{CP}}(K^+ K^-)$ has been measured with a precision of 0.2% [3], thus allowing the determination of $A_{\text{CP}}(K^0_S K^0_S)$.

1The inclusion of charge-conjugate processes is implied throughout this document, unless explicitly specified.
2 LHCb detector

The LHCb detector [11, 12] is a single-arm forward spectrometer covering the pseudorapidity range $2 < \eta < 5$, designed for the study of particles containing $b$ or $c$ quarks. The detector includes a high-precision tracking system consisting of a silicon-strip vertex detector surrounding the $pp$ interaction region, a large-area silicon-strip detector (TT) located upstream of a dipole magnet with a bending power of about $4\,\mathrm{Tm}$, and three stations of silicon-strip detectors and straw drift tubes placed downstream of the magnet. The tracking system provides a measurement of momentum, $p$, of charged particles with a relative uncertainty that varies from 0.5% at low momentum to 1.0% at 200 GeV/$c$. The minimum distance of a track to a primary vertex (PV), the impact parameter (IP), is measured with a resolution of $(15 + 29/p_T)\,\mu\mathrm{m}$, where $p_T$ is the component of the momentum transverse to the beam, in GeV/$c$. Different types of charged hadrons are distinguished using information from two ring-imaging Cherenkov (RICH) detectors. Photons, electrons and hadrons are identified by a calorimeter system consisting of scintillating-pad and preshower detectors, an electromagnetic calorimeter and a hadronic calorimeter. Muons are identified by a system composed of alternating layers of iron and multiwire proportional chambers. The magnetic field deflects oppositely-charged particles in opposite directions and this can lead to detection asymmetries. Periodically reversing the magnetic field polarity throughout the data taking almost cancels the effect. The configuration with the magnetic field pointing upwards (downwards), MagUp (MagDown), bends positively (negatively) charged particles in the horizontal plane towards the centre of the LHC ring.

The online event selection is performed by a trigger, which consists of a hardware stage, based on information from the calorimeter and muon systems, followed by a software stage, which applies a full event reconstruction. At the hardware trigger stage, events are required to have a muon with high $p_T$ or a hadron, photon or electron with high transverse-energy deposit in the calorimeters.

Simulated events are used at various phases of the analysis. In the simulation, $pp$ collisions are generated using PYTHIA [13, 14] with a specific LHCb configuration [15]. Decays of hadronic particles are described by EVTGEN [16], in which final-state radiation is generated using PHOTOS [17]. The interaction of the generated particles with the detector, and its response, are implemented using the GEANT4 toolkit [18, 19] as described in ref. [20].

3 Event selection

The 2015 and 2016 data samples collected in $pp$ collisions at 13 TeV, which correspond to about $2\,\mathrm{fb}^{-1}$ of integrated luminosity, are used in this analysis. Candidates are reconstructed in the decay $D^{*+} \rightarrow D^0\pi^+$, followed by $D^0 \rightarrow K_S^0K^0_S$ and then $K^0_S \rightarrow \pi^+\pi^-$. The hardware trigger decision is required to be based either on the transverse energy deposited in the hadronic calorimeter by a charged particle from the decay of the $D^0$ meson, or on signatures not associated with the $D^{*+}$ decay, such as a high-$p_T$ muon, or a high transverse-energy deposit in the electromagnetic or hadronic calorimeters. The first stage of the software trigger selects a sample with enhanced heavy-flavour content by requiring
the presence of a large IP, high-$p_T$ charged particle. In the second stage of the software trigger, each selected event is required to contain at least one fully-reconstructed candidate for the $D^{*+} \rightarrow D^0 \pi^+$, $D^0 \rightarrow K^0_S K^0_S$ decay.

The decays $K^0_S \rightarrow \pi^+ \pi^-$ are reconstructed in two different categories: the first involving $K^0_S$ mesons that decay early enough for the decay products to be reconstructed in the vertex detector; and the second containing $K^0_S$ candidates that decay outside the acceptance of the vertex detector, but within the TT acceptance. These categories are referred to as long and downstream, respectively. The long category has better mass, momentum and decay-vertex resolution than the downstream category. In this analysis at least one $K^0_S$ in each $D^0$ decay is required to be of the long type. There are therefore two subsamples used: one where both $K^0_S$ candidates are long and the other where one is long and the other is downstream. These are referred to as the LL and LD subsamples, and are analysed separately, since they exhibit different resolutions. One or more of the charged decay products from a long $K^0_S$ meson is required to activate the first stage of the software trigger. The pion candidates used in the $K^0_S$ reconstruction are required to be high-quality tracks, using the $\chi^2$/ndf of the track fit and the output $P_{\text{fake}}$ of a multivariate classifier, trained to identify fake tracks, that combines information from the particle identification and tracking systems.

To ensure that pion candidates do not originate from the PV, they are required to satisfy $2 \Delta IP > 36$. The quantity $2 \Delta IP$ for a given particle is defined as the difference in the vertex fit $2 \chi^2_P$ of the PV associated to the particle, reconstructed with and without the particle being considered. For downstream $K^0_S$ candidates, the pions are required to satisfy $p > 3 \text{ GeV}/c$ and $p_T > 175 \text{ MeV}/c$.

Two oppositely charged pions are used to form $K^0_S$ candidates. The vertex fit is required to satisfy $\chi^2 < 30$ and the $2 \chi^2_P$ is required to be greater than 9 (4) for long (downstream) $K^0_S$ candidates. Furthermore, long (downstream) $K^0_S$ candidates are required to satisfy $p_T > 500$ (750) MeV/c.

Two reconstructed $K^0_S$ candidates are paired to form $D^0$ candidates, requiring $2 \chi^2 < 10$ for the vertex fit. The sum of the $p_T$ of the $K^0_S$ candidates is required to exceed 1500 (2000) MeV/c for LL (LD) candidates. The angle between the $D^0$ momentum and the vector connecting the PV to the $D^0$ decay vertex is required to be less than 34.6 mrad.

An important source of background is due to the presence of $D^0 \rightarrow K^0_S \pi^+ \pi^-$ decays, where the $\pi^+ \pi^-$ pair satisfies the $K^0_S$ selection. In principle, the contribution of this channel can be substantial, due to its large branching fraction, but it is effectively reduced by placing a requirement on the $K^0_S$ flight distance (FD) and on the mass of the $K^0_S$ candidates. The quantity $\chi^2_{\text{FD}}$ is the square of the measured $K^0_S$ flight distance divided by the square of its uncertainty. Figure 2 shows a two-dimensional plot of the value of $\chi^2_{\text{FD}}$. A pion candidate ($\pi^+_{\text{tag}}$) is added to a reconstructed $D^0$ meson to form a $D^{*+}$ candidate, with a $D^{*+}$ vertex fit which is required to have $\chi^2 < 25$. The $\pi^+_{\text{tag}}$ candidate is required to have $p_T > 100 \text{ MeV}/c$, and to pass through regions of the detector that are known to have a small detector asymmetry [8]. A small fraction of $\pi^\pm_{\text{tag}}$ candidates are reconstructed with the wrong charge assignment, and are removed by a selection on track quality.

An important source of background is due to the presence of $D^0 \rightarrow K^0_S \pi^+ \pi^-$ decays, where the $\pi^+ \pi^-$ pair satisfies the $K^0_S$ selection. In principle, the contribution of this channel can be substantial, due to its large branching fraction, but it is effectively reduced by placing a requirement on the $K^0_S$ flight distance (FD) and on the mass of the $K^0_S$ candidates. the quantity \( \log \chi^2_{FD} \) for \( K^0_s \) pairs in the LL sample. In the figure, four separate regions are visible. The upper right part of the plot, where both \( K^0_s \) candidates have significant flight distances, is the \( D^0 \rightarrow K^0_s K^- \) signal, while the upper left and lower right regions correspond to \( D^0 \rightarrow K^0_s \pi^+ \pi^- \) decays. The lower left is populated by \( D^0 \rightarrow \pi^+ \pi^- \pi^+ \pi^- \) decays and combinatorial background. A requirement on \( \chi^2_{FD} \) is only necessary for long \( K^0_s \) candidates, since downstream \( K^0_s \) candidates decay far from the PV by construction.

For the LL subsample the requirement on the two \( K^0_s \) candidates (\( K^0_{s1} \) and \( K^0_{s2} \)) is

\[
[\log \chi^2_{FD}(K^0_{s1}) - 10]^2 + [\log \chi^2_{FD}(K^0_{s2}) - 10] < 16,
\]

while for the LD sample \( \log \chi^2_{FD}(K^0_{sL}) > 2.5 \) is imposed on the long \( K^0_s \) candidate.

The \( K^0_s \) mass requirements are

\[
\sqrt{[m(K^0_{s1}) - m_{K^0}]^2 + [m(K^0_{s2}) - m_{K^0}]^2} < 10.5 \text{ MeV}/c^2,
\]

for LL candidates, with \( m_{K^0} = 497.6 \text{ MeV}/c^2 \) [10], and

\[
\sqrt{\left[ \frac{m(K^0_{sL}) - m_{K^0}}{10.5 \text{ MeV}/c^2} \right]^2 + \left[ \frac{m(K^0_{sD}) - m_{K^0}}{15 \text{ MeV}/c^2} \right]^2} < 1,
\]

for LD candidates. This selection takes into account the difference in resolution between \( m(K^0_{sL}) \) and \( m(K^0_{sD}) \). The \( \log \chi^2_{FD}(K^0_s) \) and \( m(K^0_s) \) regions corresponding to signal and peaking-background candidates are identified using simulations. They are further optimised on charge-integrated data by minimising the expected statistical uncertainty on \( A^{\text{raw}} \).

Events in which the \( D^{*+} \) meson is not produced in the primary interaction, but instead is the product of a \( b \)-hadron decay, are characterised by a different production asymmetry and are treated as background. These so-called secondary \( D^{*+} \) candidates tend to have

\[ \text{Figure 2. Two-dimensional distribution of the logarithm of the } K^0_s \text{ flight distance significance (} \log \chi^2_{FD} \text{) for the two } K^0_s \text{ candidates in the LL subsample of } D^0 \rightarrow K^0_s K^- \text{ decays. The } D^0 \rightarrow K^0_s K^- \text{ signal can be observed in the upper right region of the plot. The contour corresponds to eq. (3.1).} \]
larger values of $\chi^2_{IP}(D^0)$ than prompt $D^{*+}$ candidates and are suppressed by requiring $\log \chi^2_{IP}(D^0) < 3.0$ (3.5) for the LL (LD) subsample. The requirement $\log \chi^2_{IP}(\pi^+_{\text{tag}}) < 2.5$ is imposed on both subsamples. Simulated events are used to estimate the residual secondary fraction in the LL and LD subsamples to be 9% and 13%, respectively.

A multivariate classifier, based on the k-nearest neighbours (kNN) algorithm [21], is used to further suppress combinatorial background. The kNN algorithm classifies events according to the fraction of signal events among its $k$ nearest neighbours (taken from the training sample of signal and background events), where the distance is calculated in the $n$-dimensional space of the input variables and $k$ is a positive integer. The training sample uses simulated events for the signal and data events from the $D^0$ mass sidebands for the background. A wide range of input variables based on track and vertex quality, the transverse momenta of $K^0_S$ and $D^0$ candidates, helicity angles of the $K^0_S$ and $D^0$ decays and particle identification information on the pions in the $D^0$ decays was initially considered. Variables depending on the $\pi^\pm_{\text{tag}}$ track are not included in the classifier to avoid introducing possible bias on the asymmetry measurement. The actual variables used, the value of $k$, and the selection on the classifier output are optimised separately for the LL and LD subsamples, using the expected statistical uncertainty on the raw asymmetry as a figure of merit.

For the $D^0 \rightarrow K^+K^-$ control channel, an attempt is made to keep the selection similar to the $D^0 \rightarrow K^0_SK^0_S$ channel, although some selections made at the software trigger level are different for the two channels. Charged tracks positively identified as kaons in the RICH detectors are selected to reconstruct $D^0$ candidates. The kaons are required to satisfy $\chi^2_{IP} > 4$. For the $D^0$ candidates, at least one of the kaons is required to have $p_T > 1$ GeV/c. The sum of the kaon momenta is required to exceed 5 GeV/c and the $D^0$ $p_T$ is required to be at least 1 GeV/c. Furthermore, the angle between the $D^0$ momentum vector and the vector connecting the primary and decay vertices is required to be less than 17.3 mrad. The following selections are the same as for the $D^0 \rightarrow K^0_SK^0_S$ channel: $\pi^\pm_{\text{tag}}$ fiducial cuts, fake-track probability and $\chi^2_{IP}$ selection; and requirements on $D^0 \chi^2_{IP}$ and invariant mass.

4 Asymmetry measurement

The raw asymmetry for $D^0 \rightarrow K^0_SK^0_S$ is determined by separating the selected candidates into subsets tagged by positively and negatively charged pions. A simultaneous unbinned maximum likelihood fit to their $\Delta m$ distributions is performed, where $\Delta m$ is the difference of the reconstructed invariant mass of the $D^{*+}$ and the $D^0$ candidates. The calculation of $\Delta m$ is made after the full decay chain has been reconstructed using a mass constraint on the $K^0_S$ candidates and constraining the $D^{*+}$ candidate to originate from the PV.

The signal shape is modelled using the Johnson $S_U$ distribution [22], which consists of a core Gaussian-like shape but allows for an asymmetric tail

$$S(x; \mu, \sigma, \delta, \gamma) \propto \left[ 1 + \left( \frac{x - \mu}{\sigma} \right)^2 \right]^{-\frac{1}{2}} \times \exp \left\{ -\frac{1}{2} \left[ \gamma + \delta \sinh^{-1} \left( \frac{x - \mu}{\sigma} \right) \right]^2 \right\}. \quad (4.1)$$
The background shape is described with an exponential function multiplied by a threshold factor and is zero below a fixed endpoint, which is set to the pion mass $m_\pi$:

$$B(x; m_\pi, \chi) \propto \sqrt{x - m_\pi} \times \exp \left( \frac{x}{m_\pi} \right).$$

The likelihood function is parametrised in terms of $A_{\text{CP}}$ and the expected total number of events $N_{\text{exp}} = n_{\text{sig}} + n_{\text{bkg}}$

$$L = \frac{e^{-N_{\text{exp}}}}{N_{\text{obs}}!} \prod_i \left[ n_{\text{sig}} \frac{1 + q_i A_{\text{raw}}^{\text{sig}}}{2} S(\Delta m) + n_{\text{bkg}} \frac{1 + q_i A_{\text{raw}}^{\text{bkg}}}{2} B_q(\Delta m) \right],$$

where $n_{\text{sig}}$ and $n_{\text{bkg}}$ are the signal and background yields, respectively, and the parameter $q_i = \pm 1$ is the charge of the $D^{*\pm}$ candidate and $N_{\text{obs}}$ is the total number of candidates.

The signal raw asymmetry $A_{\text{raw}}^{\text{sig}}$ is a free parameter in the fit. The free parameter $A_{\text{raw}}^{\text{bkg}}$ allows for a possible asymmetry in the combinatorial background. The four parameters in eq. (4.1) defining the signal probability distribution function (PDF) are common to the $D^{0}$ and $D^{*0}$ samples, while the parameter describing the background shape is allowed to differ between the two subsamples. For the LL sample, there are ten free parameters. To achieve convergence of the fit in the smaller LD sample, it is necessary to fix the two parameters that describe the asymmetric tail in the signal PDF to the values obtained from the charge-integrated LL subsample. Based on studies of simulated events, the tail parameters of the LL and LD subsamples are expected to be compatible. Separate fits are performed for the two magnet polarities.

Table 1 shows the results of the simultaneous fits to the $D^0 \rightarrow K^0_S K^0_S$ candidates. The results on each subset of the data are compatible with each other. The fit is shown in figure 3 for the samples collected with the MagUp magnetic field configuration.

For the $D^0 \rightarrow K^+ K^-$ channel, binned $\chi^2$ fits are performed to the $\Delta m$ distributions of the positively and negatively tagged $D^0$ decays. The sample consists of $8.25 \times 10^5$ selected candidates for the MagDown magnet polarity and $5.61 \times 10^5$ candidates for the MagUp magnet polarity. The signal is modelled with a Johnson $S_U$ distribution plus a Gaussian distribution, while the background shape is described by a fourth-degree polynomial multiplied by a $\sqrt{\Delta m - m_\pi}$ threshold factor. There are 12 free parameters, and 150 bins.
in each \(\Delta m\) fit. The \(\chi^2\) probabilities associated to the fits are 28\% (20\%) for the negatively (positively) tagged \(D^0\) decays, and 23\% (3\%) for the negatively (positively) tagged \(D^0\) decays, in the MagUp and MagDown magnet polarities, respectively. Figure 4 shows the results for the MagUp magnet polarity fit. The results obtained for the two magnet polarities are

\[
A^{\text{raw}}(K^+K^-)_{\text{MagUp}} = -0.0188 \pm 0.0020, \tag{4.4}
\]

\[
A^{\text{raw}}(K^+K^-)_{\text{MagDown}} = 0.0030 \pm 0.0017,
\]

where the uncertainties are statistical. The difference in the MagUp and MagDown values of \(A^{\text{raw}}(K^+K^-)\) is an indication of a significant \(\pi_{\text{tag}}^\pm\) detection asymmetry, which depends on the magnetic field orientation.

5 Systematic uncertainties

The main source of systematic uncertainty arises from the determination of \(A^{\text{raw}}\) on the \(D^0 \rightarrow K^0_s K^0_s\) sample. Possible bias in the fitting procedure is evaluated using simulated pseudoexperiments. In particular, the uncertainty related to the choice of the signal model is evaluated by using the nominal model to fit samples generated with two alternative
Figure 4. Results of fits to $\Delta m$ distributions of $D^0 \rightarrow K^+ K^-$ candidates for the MagUp magnet polarity. The fits to (a) $D^{*+} \rightarrow D^0 \pi^+$ candidates and (b) $D^{*-} \rightarrow \bar{D}^0 \pi^-$ candidates are shown. The black points represent the data, the dashed blue and solid blue curves represent the background component and the total fit function, respectively.

models for the signal PDF: either a sum of two Gaussians with a common mean (for the LL sample) or a single Gaussian (for the LD sample). The background PDF is varied by modifying its behaviour at threshold. Systematic uncertainties of $5 \times 10^{-3}$ and 0.01 for the LL and LD samples, respectively, are assigned based on this study. As a cross-check, the background shapes are constrained to be the same for the $D^{*+}$ and $D^{*-}$ samples, and the resulting asymmetry is compatible with the nominal. For the $D^0 \rightarrow K^+ K^-$ fit, an alternative procedure is used to evaluate the systematic uncertainty associated with the signal PDF. In this case, the signal region ($\pm 2.5$ MeV/$c^2$ around the signal mean) is excluded and only the background shape is fit. The yield is then determined by estimating the background in the signal region by interpolating the fitted background function. Additionally, alternative background shapes are tried, varying the degree of the polynomial. Based on these studies a systematic uncertainty of $2 \times 10^{-3}$ is assigned to $A^{raw}_{raw}(K^+ K^-)$.

The contribution of the residual background of $D^0 \rightarrow K^0_S \pi^+ \pi^-$ decays to the fitted LL and LD signal yields is estimated to be (3.5 ± 0.7)% and (5.5 ± 4.6)%, respectively. These values are combined with the $K^0_S \pi^+ \pi^-$ background asymmetry, determined from background-dominated regions of the $\chi^2_{FD}$ distributions, to estimate contributions to the systematic uncertainty of $4 \times 10^{-3}$ and $5 \times 10^{-3}$, for the LL and LD samples. Another contribution comes from the residual fraction of secondary decays, which leads to a systematic uncertainty for this source of $2 \times 10^{-3}$ and $3 \times 10^{-3}$ for the LL and LD samples. In this case an upper limit of 0.02 for the maximum difference in the production asymmetries of $D^{\pm}$ mesons and $b$-hadrons is assumed [23–25].

Potential trigger biases are studied using tagged $D^0 \rightarrow K^+ K^-$ decays, by comparing the raw asymmetries obtained in the subsample in which the trigger decision is based on the charged particles from the decay of the $D^0$ meson, and in the subsample in which the trigger decision is not associated with the $D^{*+}$ decay. The sum in quadrature of the difference (albeit not statistically significant) and of its statistical uncertainty is assigned as a systematic uncertainty, which accounts for residual trigger-induced biases in the difference of measured asymmetries for signal and control channels. This uncertainty amounts to
$5 \times 10^{-3}$ for both the LL and LD samples. The small probability of assigning the wrong charge to the $\pi^\pm_{\text{tag}}$ candidate results in a systematic uncertainty of $2 \times 10^{-3}$ for both the LL and LD samples. This is obtained by varying the selection on the $P_{\text{fake}}$ value of $\pi^\pm_{\text{tag}}$ candidates. This uncertainty cancels for $A^{\text{CP}}$. For each neutral kaon in the final state, asymmetries arising from regeneration and from mixing and $CP$ violation in the $K^0 - \bar{K}^0$ system are suppressed at the $O(10^{-3})$ level [26]. Since they are expected to affect $D^0 \to K^0 S K^0 S$ and $\bar{D}^0 \to K^0 S K^0 S$ decays by the same amount, they cancel in $A^{\text{raw}}$ and therefore do not contribute to the systematic uncertainty.

The cancellation of the production and detection asymmetries in the computation of $\Delta A^{\text{CP}}$ may not be perfect due to differences in the kinematics of the $D^0 \to K^0 S K^0 S$ candidates and the $D^0 \to K^+ K^-$ candidates. The offline selection of the two channels aims to keep the kinematics as similar as possible, but the different trigger selections on the final states can introduce differences. The associated systematic uncertainty is evaluated by considering four kinematic variables: the transverse momentum and the pseudorapidity of the $D^+$ candidate and the $\pi^+_{\text{tag}}$ candidate, respectively. For each variable a one-dimensional weighting is performed on the $D^0 \to K^+ K^-$ events such that they have the same distribution as the $D^0 \to K^0 S K^0 S$ sample. Then $A^{\text{raw}}(K^+ K^-)$ is determined from the weighted sample. This is repeated for each of the four kinematic variables. The largest change in $A^{\text{raw}}(K^+ K^-)$ is taken as the systematic uncertainty and this is found to be $2 \times 10^{-3}$ for both the LL and LD samples. The systematic uncertainties are summarised in table 2.

### Table 2. Systematic uncertainties on the quantities $A^{\text{raw}}$ and $\Delta A^{\text{CP}}$. The total systematic uncertainties in the last row are obtained by summing the corresponding contributions in each column in quadrature. Uncertainties are expressed in units of $10^{-3}$.

6 Results

The procedure described in section 1 is used to combine the results for the raw asymmetries to obtain $A^{\text{CP}}(K^0 S K^0 S)$ for each of the LL and LD subsamples. For each of the subsamples, the difference $\Delta A^{\text{CP}}$ is calculated separately for the different magnet polarities using the fitted values of $A^{\text{raw}}$ (table 1 and eq. (4.4)). The values of $\Delta A^{\text{CP}}$ corresponding to the two magnet polarities, which are found to be in good agreement (figure 5), are averaged
Figure 5. Values of $\Delta A^{CP}$ obtained for both magnet polarities on the LL and LD samples, along with the average of these measurements. Only statistical uncertainties are shown.

by weighting with their statistical uncertainties. The systematic uncertainties are taken from table 2. Using the LHCb measurement of $A^{CP}(K^+ K^-) = (0.04 \pm 0.12 \pm 0.10)\%$ [3] results in

$$A^{CP}(LL) = 0.067 \pm 0.038 \pm 0.009,$$
$$A^{CP}(LD) = -0.053 \pm 0.074 \pm 0.013,$$

where the first uncertainty is statistical and the second is systematic. These results are combined by performing an average weighted by the total uncertainties and assuming that the systematic uncertainties are fully correlated. The final result is

$$A^{CP}(K^0_S K^0_S) = 0.043 \pm 0.034 \pm 0.010.$$

This measurement is systematically independent of the LHCb Run 1 measurement, $A^{CP}(K^0_S K^0_S) = -0.029 \pm 0.052 \pm 0.022$ [8], and is compatible with it. An average, weighted by the total uncertainties, of the two measurements is performed to obtain

$$A^{CP}(K^0_S K^0_S) = 0.023 \pm 0.028 \pm 0.009.$$

These results are compatible with the expectations of the Standard Model [5] and with previous measurements [7, 9].

Acknowledgments

We express our gratitude to our colleagues in the CERN accelerator departments for the excellent performance of the LHC. We thank the technical and administrative staff at the LHCb institutes. We acknowledge support from CERN and from the national agencies: CAPES, CNPq, FAPERJ and FINEP (Brazil); MOST and NSFC (China); CNRS/IN2P3 (France); BMBF, DFG and MPG (Germany); INFN (Italy); NWO (Netherlands); MNiSW and NCN (Poland); MEN/IFA (Romania); MinES and FASO (Russia); MinECo (Spain); SNSF and SER (Switzerland); NASU (Ukraine); STFC (United Kingdom); NSF (USA). We acknowledge the computing resources that are provided by CERN, IN2P3 (France), KIT and DESY (Germany), INFN (Italy), SURF (Netherlands), PIC (Spain), GridPP (United
Kingdom), RRCKI and Yandex LLC (Russia), CSCS (Switzerland), IFIN-HH (Romania), CBPF (Brazil), PL-GRID (Poland) and OSC (USA). We are indebted to the communities behind the multiple open-source software packages on which we depend. Individual groups or members have received support from AvH Foundation (Germany), EPLANET, Marie Skłodowska-Curie Actions and ERC (European Union), ANR, Labex P2IO and OCEVU, and Région Auvergne-Rhône-Alpes (France), Key Research Program of Frontier Sciences of CAS, CAS PIFI, and the Thousand Talents Program (China), RFBR, RSF and Yandex LLC (Russia), GVA, XuntaGal and GENCAT (Spain), Herchel Smith Fund, the Royal Society, the English-Speaking Union and the Leverhulme Trust (United Kingdom).
